

Uranium Series, Rates of Basaltic Melt Generation and Transport

Aaron J. Pietruszka*

Denver Federal Center, U.S. Geological Survey, Denver, CO, USA

Synonyms

Basalt genesis; Mantle melting; Time scales of magmatic processes; Uranium-series isotope disequilibrium

Definitions

Uranium-series isotope disequilibrium. A state in which the activities (i.e., decay rates) of the short-lived daughter isotopes of radioactive ^{238}U or ^{235}U are different from their longer-lived parent isotopes in a geological sample due to a physical or chemical process (e.g., partial melting of the Earth's mantle) that changed the proportions of the elements of interest.

Magma. A molten, incandescent (hot), subterranean silicate fluid composed of melt and, in most cases, suspended mineral crystals and gas bubbles that may cool slowly within the Earth's crust to form an intrusive igneous rock or erupt at a volcano as lava or tephra.

Basalt. A mafic volcanic rock (lava) that forms when a magma with relatively high concentrations of magnesium and iron and a relatively low concentration of silicon (<52 wt% SiO_2) erupts onto the surface of the Earth.

Magmatic processes. The series of events that create and modify magma, including the generation of melt within the mantle and its modification prior to eruption due to crystallization, degassing, mixing, and/or assimilation of the surrounding rock.

Introduction

Short-lived uranium (U)-series isotopes are powerful tracers of the rates and mechanisms of basaltic melt generation and transport because their half-lives ($T_{1/2}$) are thought to be similar to the time scales of magmatic processes. The U-series isotopes that are most commonly applied to basalt genesis are ^{230}Th ($T_{1/2} = 75,700$ years), ^{231}Pa ($T_{1/2} = 32,800$ years), ^{226}Ra ($T_{1/2} = 1,600$ years), and ^{210}Pb ($T_{1/2} = 22$ years). The Earth's mantle (prior to melting) is generally thought to lie in a state of radioactive equilibrium in which the decay rates of these short-lived isotopes are equal to their long-lived, radioactive parents (either ^{238}U with $T_{1/2} = 4.5$ Gyr or ^{235}U with $T_{1/2} = 0.7$ Gyr). Magmatic processes, such as partial melting of the mantle, may change the relative proportions of these elements and create a state of radioactive disequilibrium between one or more parent-daughter U-series isotope pairs. Depending on the nature of the process involved, this elemental fractionation leads to a faster (relative) rate of decay for one of the isotopes in a pair. The isotope with a faster rate of decay rate is said to have an “excess” (e.g., excess ^{230}Th), whereas the isotope with a slower rate of decay is said to have a “deficit” (e.g., a deficit of ^{238}U). The magnitude of this disequilibrium in

*Email: apietruszka@usgs.gov

basalts is often a function of time-dependent phenomena, such as the rate of melt generation or the rate of mantle upwelling. In this summary, studies of U-series disequilibrium in basalts from three main tectonomagmatic environments are reviewed: mid-ocean ridges, intraplate oceanic volcanoes, and volcanic island arcs.

Mid-ocean Ridge Basalts

Mid-ocean ridge basalts (MORB) form due to partial melting of the uppermost mantle as a passive response to seafloor spreading. Young MORB display a wide range of negatively correlated ^{226}Ra - ^{230}Th and ^{230}Th - ^{238}U disequilibria with up to ~300 % excess ^{226}Ra and ~30 % excess ^{230}Th (e.g., Rubin and Macdougall 1988; Lundstrom et al. 1999; Sims et al. 2002). These signatures are thought to derive from the partial melting of the mantle over a range of depths (Lundstrom et al. 1999; Sims et al. 2002) at rates of solid mantle upwelling of ≤ 5 cm/year (e.g., Jull et al. 2002). Excesses of ^{230}Th and ^{226}Ra are likely created by a slow rate of melting at the bottom of the melting region in the stability field of garnet. The initial ^{226}Ra - ^{230}Th disequilibrium likely returns to radioactive equilibrium during melt transport through the mantle due to the short $T_{1/2}$ of ^{226}Ra , but the ^{230}Th excesses are preserved because much of the melt rises relatively quickly (relative to the $T_{1/2}$ of ^{230}Th) to the surface in chemically isolated channels (Lundstrom et al. 1999; Jull et al. 2002; Sims et al. 2002). In contrast, the final excesses of ^{226}Ra in MORB probably require the rapid extraction of melts that were recently in chemical equilibrium with the garnet-free top of the melting region, where no ^{230}Th excesses are produced (Lundstrom et al. 1999; Jull et al. 2002; Sims et al. 2002). The large excesses of ^{226}Ra in MORB constrain the maximum time scale from melting to eruption to be less than a few thousand years (Rubin and Macdougall 1988). However, deficits of ^{210}Pb (relative to ^{226}Ra) up to 15 % in zero-age MORB may require transport times from the source to the surface of only a few decades, if these ^{210}Pb - ^{226}Ra disequilibria are created during partial melting of the mantle (Rubin et al. 2005).

Intraplate Oceanic Basalts

Partial melting of the actively upwelling mantle at hot spots, such as the Hawaiian Islands (Pacific Ocean), Réunion Island (Indian Ocean), or the Galapagos Archipelago (Pacific Ocean), forms intraplate oceanic basalts. These melting anomalies are not directly tied to plate tectonics (unlike mid-ocean ridges and island arcs). Instead, this type of volcanism is thought to be related to the upwelling of mantle plumes that partially melt near the base of the oceanic lithosphere. A good example of intraplate oceanic basalts comes from the Hawaiian Islands, where a mantle plume is thought to be located under the Island of Hawai'i. This island comprises five volcanoes (Kīlauea, Mauna Loa, Mauna Kea, Hualālai, and Kohala), and a volcanically active seamount lies offshore (Lō'ihi). Unlike MORB, basaltic lavas from Hawaiian volcanoes possess relatively small ^{226}Ra excesses (up to only ~30 %) and variable ^{230}Th excesses that range from near equilibrium to MORB-like values up to 30 % (e.g., Sims et al. 1999; Pietruszka et al. 2001, 2011). The range in ^{230}Th - ^{238}U disequilibria for Hawaiian basalts is thought to be derived from a wide range in the rate of mantle upwelling and melting. The highest rates create the smallest ^{230}Th - ^{238}U disequilibria that are preserved in the lavas erupted near the central axis of the plume (Kīlauea and Mauna Loa). The lowest rates create the largest ^{230}Th - ^{238}U disequilibria that are preserved in lavas erupted from the margin of the plume (Lō'ihi, Hualālai, and Haleakalā, a volcano on the Island of Maui that was

active in recent prehistoric times). For example, the rate of mantle upwelling based on U-series isotope disequilibria is estimated to vary from up to 1,000 cm/year near the axis of the Hawaiian plume to ~5–6 cm/year near its margin (Sims et al. 1999; Pietruszka et al. 2001, 2011). This sort of zonation in the rate of mantle upwelling and melting for plume-derived lavas has also been observed in hot spot-related basalts from Iceland (Peate et al. 2001; Kokfelt et al. 2003). A general inverse correlation between ^{230}Th - ^{238}U disequilibria and inferred plume flux has been found for oceanic basalts from around the world (Chabaux and Allègre 1994; Bourdon et al. 2006).

Mafic Volcanic Rocks from Island Arcs

Mafic island arc magmas form at intra-oceanic subduction zones when aqueous fluids are released from the subducting slab (formerly altered oceanic crust) into the overlying mantle wedge, which leads to partial melting of the metasomatized upper mantle. Volcanic rocks from island arcs often have larger ^{226}Ra - ^{230}Th disequilibria (up to 500 %) than MORB or intraplate oceanic basalts (Turner et al. 2001) and an unusually wide range of ^{230}Th - ^{238}U disequilibria from up to ~30 % excess ^{230}Th to ~60 % excess ^{238}U (e.g., Elliott et al. 1997; Turner et al. 1997). The latter signature of excess ^{238}U (relative to ^{230}Th) is not found, even in small amounts, in the vast majority of MORB or intraplate oceanic basalts. The enrichments in ^{226}Ra and ^{238}U in island arc magmas are thought to result from the mobilization of these elements into slab-derived aqueous fluids (released during the dehydration of the subducting slab) and their introduction into the overlying mantle wedge prior to partial melting (e.g., Condomines and Sigmarsson 1993; Elliott et al. 1997; Turner et al. 1997; Sigmarsson et al. 2002; Bourdon et al. 2003; Dosseto and Turner 2013). The exceptionally large ^{226}Ra - ^{230}Th disequilibria preserved in young lavas from island arcs constrain the time scale of melt transport to only a few hundred years (from mantle source to surface), and the velocity of melt transport to ~1,000 m/year (Turner et al. 2001).

Summary

The U-series isotopic disequilibria of basaltic lavas allow the rates and mechanisms of basaltic melt generation and transport to be determined. These time-dependent phenomena, such as the rates of mantle upwelling or the time scales of melt transport beneath the active volcanic systems discussed above, would be difficult, if not impossible, to quantify using conventional geochemical tracers of the melt-generation process, such as stable, incompatible trace elements.

Model Ages (Sm-Nd)

Alan P. Dickin*

School of Geography and Earth Sciences, McMaster University, Hamilton, ON, Canada

Definition

A neodymium model age is an estimate of the age of “crustal formation” based on the assumption of a model composition for the mantle source. It is most commonly used to date the ages of crustal terranes within Precambrian orogenic belts or to estimate the provenance age of clastic sedimentary rocks.

Introduction

Nd model age dating is probably the most misunderstood of the major geological dating methods. As the name indicates, Nd model ages are dependant on a mantle model to determine ages, and their accuracy is therefore dependant on the suitability of the mantle model. Nd model ages also have relatively large analytical uncertainties of around ± 20 Myr. However, they are uniquely powerful in determining crustal formation ages, representing the time when crustal blocks were first created by mantle-derived magmatism, most commonly above subduction zones. In contrast, the U-Pb dating method provides much more precise and accurate ages for igneous crystallization, but can only provide a minimum age for crustal formation, since it cannot date the time of crustal separation from the mantle.

Historical Development

Nd model ages were conceived by DePaolo and Wasserburg (1976b), based on the observation by DePaolo and Wasserburg (1976a) that the initial ratios of terrestrial igneous rocks appeared to lie on the same Nd isotope growth curve as chondritic meteorites. Hence, they inferred that the mantle source of terrestrial igneous rocks had a uniform “Bulk Earth” signature equivalent to a Chondritic Uniform Reservoir (CHUR).

Since Nd and Sm are rare earth elements (REE) with very similar chemistry, it was inferred that within magmatic systems, these elements only undergo significant relative fractionation at low percentages of melting, such as when magmas are first extracted from the mantle. Since Nd is the more incompatible of the two elements, the process of “crustal extraction” or “crustal formation” leads to a markedly lower Sm-Nd ratio in crustal rocks relative to the mantle. In contrast, subsequent intra-crustal differentiation processes are not thought to cause significant further Sm-Nd fractionation. This leads to the scenario shown in Fig. 1.

*Email: dickin@mcmaster.ca

Fig. 1 Plot of Nd isotope evolution against time, showing the concept of Nd model ages based on the intersection of the isotopic growth line of the sample with that of the Bulk Earth, based on a chondritic model. McCulloch and Wasserburg (1978) and Dickin (2005)

The determination of the Nd isotope ratio and Sm-Nd ratio of a single crustal rock, presumed to have been an effectively closed system since crustal extraction, allows its Nd isotope growth line to be extrapolated back to its intersection with the CHUR evolution line, so that the point of intersection yields a T_{CHUR} model age for the analyzed sample. Algebraically, the age is defined as follows:

$$T_{\text{CHUR}} = \frac{1}{\lambda} \ln \left| 1 + \frac{\frac{(^{143}\text{Nd})^0}{(^{144}\text{Nd})_{\text{sample}}} - \frac{(^{143}\text{Nd})^0}{(^{144}\text{Nd})_{\text{CHUR}}}}{\frac{(^{147}\text{Sm})^0}{(^{144}\text{Nd})_{\text{sample}}} - \frac{(^{147}\text{Sm})^0}{(^{144}\text{Nd})_{\text{CHUR}}}} \right|$$

The non-deviation of the crustal growth line through metamorphic and sedimentation events in Fig. 1 is a schematic representation of the closed-system concept. Empirical evidence suggests that given an adequate-sized whole-rock sample of suitable chemistry, Sm-Nd systematics are resistant to high-grade metamorphism, even under severe deformation (e.g., Barovich and Patchett 1992). The Sm-Nd system may also remain unfractionated through erosion-sedimentation events, although the integrity of the system depends on the type and conditions of sedimentation. Clastic sediments have been shown to give good results, but chemical sediments have not (e.g., Bock et al. 1994).

In their pioneering demonstration of the Nd model age method, McCulloch and Wasserburg (1978) applied the model age dating technique to composite samples of the Canadian Shield, in order to achieve maximum coverage from a limited number of samples. They showed that Archean crust is preserved in several Proterozoic orogenic belts for which other dating systems (e.g., Rb-Sr and K-Ar) had been reset.

Problems with the chondritic earth model appeared when young oceanic volcanics were shown to deviate from the Bulk Earth composition, reflecting sources in the depleted upper mantle. It was realized that such a depleted mantle was an inevitable result of crustal extraction over earth history, leaving an incompatible-depleted residue with a higher Sm-Nd ratio than Bulk Earth (see vector in Fig. 1).

Fig. 2 Plot of Nd isotope ratio against time using the epsilon notation, which normalizes Nd isotope ratios relative to CHUR (epsilon Nd = part per 10,000 deviation from the CHUR line). The plot shows DePaolo's quadratic curve for depleted mantle evolution and the effects of subsequent intra-crustal melting to form granite batholiths such as Boulder Creek and Pikes Peak (After DePaolo (1981) and Dickin (2005))

To solve this problem, DePaolo (1981) derived an empirical model for a “depleted mantle” reservoir, which he believed would be typical of the asthenospheric “mantle wedge” that provides the source for subduction-related magmatism. He fitted a quadratic equation to three points to model this DM source: a chondritic source at 4.57 Ga, the juvenile Paleoproterozoic Idaho Springs Formation, and modern island arcs (Fig. 2). Although the model was ad hoc, the resulting T_{DM} ages have often yielded surprising accurate estimates of the crustal formation ages of major crustal blocks, when compared with other geochronological or geological evidence.

Controversies

Apart from the assumption of the mantle model and the closed-system assumption, the other major assumption of Nd model ages is that the crustal sample in question was extracted from the mantle during a single event. This is a good assumption for the formation of geological provinces such as the Superior Province of the Canadian Shield, which largely consists of a collage of accreted oceanic arcs (Hoffman 1989). However, continental margin arcs such as the Andes (ensialic arcs) are notorious for complex magmatic mixing of components with different ages (e.g., Mamani et al. 2010). If such samples are used to calculate Nd model ages, the result can be meaningless mixed ages (Fig. 3).

A warning against such mixed ages was given by Arndt and Goldstein (1987), in their notorious paper “The use and abuse of Nd crust formation ages.” The warning was perhaps necessary, because in their haste to characterize vast areas of continental crust with a very few Nd model ages, authors such as Nelson and DePaolo (1985) had cut corners and reached some erroneous conclusions. For example, they characterized the crustal formation age of the Penokean event as 2.3 Ga, based on a chance clustering of three Nd model ages with this value from Michigan. Unfortunately, the geological community became so obsessed by this warning that later estimates of crustal formation age would be questioned (e.g., Hanmer et al. 2000), even if based on much larger Nd data sets yielding consistent results.

Fig. 3 Nd isotope evolution diagram using the epsilon notation, schematically showing the effects of Nd mixing to generate a composite sample whose Nd model age may not correspond with any real geological event (After Arndt and Goldstein (1987) and Dickin (2005))

Some Ground Rules for Future Work

In their critique, Arndt and Goldstein (1987) argued that Nd model ages should only be interpreted as true crustal formation ages “if they coincide with U-Pb zircon ages or other independent evidence of an orogenic event.” This is actually a misleading claim, which has led to additional confusion. An orogenic event is most often a collisional event and may not be a significant crust-forming event. A good example is the Grenville Orogeny, during which essentially *no* new crust was extracted from the mantle (Dickin et al. 2010). In such circumstances, large numbers of U-Pb ages may be generated that significantly post-date crustal formation (e.g., McNutt and Dickin 2012).

Ideally, if Nd model ages are used to determine the crustal formation age of accreted oceanic arc fragments (perhaps in a Precambrian crustal terrane), we may hope that U-Pb ages will be recovered that date igneous crystallization within the original arc. In that case, Nd model ages may coincide with U-Pb ages. However, even this scenario is oversimplified. The typical granitoid rocks that make up the bulk of the continental crust (tonalites and granodiorites) cannot be direct products of the mantle. When Nd model ages are determined on such material, they are probably dating their mafic crustal precursors, which may be millions of years older than the crystallization age of the plutons. Since it may take 50 Myr to create a mature island arc, we should expect that the Nd model ages for juvenile terranes may be 50 Myr older than the oldest U-Pb ages, which therefore provide only a *minimum* age for crustal formation. Therefore, if TDM model ages fall within 100 Myr or so of U-Pb zircon ages, this provides good evidence that we have a juvenile arc terrane (e.g., Daly and McLelland 1991).

If Nd model ages are more than 100 Myr older than the oldest U-Pb age, this may mean that an original accreted arc terrane was subsequently involved in a continental margin arc. Such arcs may generate pervasive magmatic reworking that almost completely masks the older crust-forming event. A good example is the 1.65 Ga Labradorian Orogeny of eastern Canada, which was partly established on an older 1.9 Ga Makkovikian accreted margin. For many years, the only evidence for the older event was the observation of ca. 2 Ga TDM model ages (Dickin 2000). However, pre-Labradorian U-Pb ages eventually confirmed the accuracy of the TDM ages as accurate estimates of the crustal formation age of the crust (Gower et al. 2008).

Fig. 4 Nd isotope evolution diagrams using the epsilon notation, showing data for the Lewisian gneisses of NW Scotland. **(a)** initial ratios for three isochron sets, **(b)** growth lines for individual samples comprising the tonalitic gneiss isochron (After Whitehouse (1988) and Dickin (2005))

Nd Model Ages and Isochron Ages

Contrary to popular belief, Sm-Nd isochrons are another valid way of testing Nd model ages. When a system is disturbed or mixed, it is unlikely that model ages and isochron ages will be affected in the same way. An illustration of these effects during high-grade metamorphism is shown in Fig. 4 (Whitehouse 1988). In this case, the Sm-Nd isochron age of Lewisian intermediate and granitic gneisses from NW Scotland was reset by high-grade metamorphism, causing the initial ratio of the isochron to lie off the DM line (Fig. 4a). However, the model ages of these rocks still approximately indicate their crustal formation age of 2.9 Ga (Fig. 4b), consistent with isochron ages for associated mafic gneisses.

An example where Nd model ages and isochron ages are consistent is provided by Mesoproterozoic gray gneisses from the Grenville province of Quebec. A suite of over 70 such gneisses from an area of nearly 100,000 km² gave a Sm-Nd isochron age of 1.51 $\pm$ 0.05 Ga and an average model age of 1.57 Ga (Dickin et al. 2010). These two ages are essentially within error and therefore validate the DM mantle model, suggesting that the suite represents a juvenile arc terrane extracted from the mantle over a few tens of millions of years around 1.5 Ga. This is confirmed by published U-Pb data within this terrane, yielding ages as old as 1.45 Ga (see references in Dickin 2000).

Conclusions

Nd model ages are uniquely powerful in providing an estimate of the formation age of Precambrian crustal terranes. They rely on geological assumptions and can therefore lead to erroneous ages if not correctly applied. However, given adequate sample sizes to test for effects such as mixing and disturbance, they can yield geologically accurate estimates for the time of crustal extraction from the mantle.

Luminescence, Fluvial Sediments

Amanda Keen-Zebert*

Division of Earth and Ecosystem Sciences, Desert Research Institute, Reno, NV, USA

Definition

The use of luminescence techniques to determine the depositional age of sediments transported and deposited by rivers and other fluvial systems.

Introduction

Dating fluvial sediments with luminescence techniques has utility to a wide range of applications such as investigating fluvial processes and alluvial stratigraphy or dating fluvial sediments as proxies of climate, environmental and sea-level change, tectonic activity, and the age of archaeological sites. Thorough reviews of luminescence applications to fluvial sediments and the typical problems encountered in doing so are provided by Wallinga (2002), Jain et al. (2004), and Rittenour (2008). The earliest attempts to date fluvial sediments using luminescence were published by Murray et al. (1995). Since then, equipment and procedural advances, particularly the single aliquot regenerative dose (SAR) technique (Murray and Wintle 2000) and the ability to measure single grains (see Bøtter-Jensen et al. 2000), have improved the capability to measure multiple equivalent doses (D_e) from smaller and single grain aliquots quickly, thereby improving the ability to detect heterogeneous bleaching and to date fluvial sediments.

Heterogeneous bleaching (also referred to as partial or incomplete zeroing, or resetting) of the luminescence signals during transport is a common problem in the accurate determination of D_e in fluvial systems because of the attenuation of light through water and water-sediment mixtures. Fluvial sediments are particularly susceptible to type B partial bleaching (Duller 1994), in which grains in a sample are bleached to different degrees, resulting in significant scatter in the distribution of D_e and a high likelihood of overestimating of the true burial age. Contributing factors include varied modes of transport, whether by suspension, saltation, or bedload; rapid erosion associated with floods; and inputs from non-bleached and older deposits such as alluvial channel banks and beds, bedrock banks and beds, and the breakdown of larger clasts into sand sized and smaller particles through mechanical wear and abrasion during transport.

Although partial bleaching is likely in fluvial environments, some studies report well-bleached sediments evidenced by either strong agreement with independent age control or tightly clustered Gaussian D_e distributions (e.g., Murray 1996; Stokes et al. 2001; Kale et al. 2000; Kar et al 2001; Rittenour et al. 2003, 2005; Leigh et al. 2004). Possible explanations for well-bleached sediments in fluvial environments include transport during seasons or in systems with low turbidity and slack water or overbank deposition in environments where sediments may lay at the surface exposed to sunlight for some time after deposition before burial.

*Email: keenzebert@gmail.com

In dating fluvial sediments, it is necessary to test for the presence of partial bleaching and, when present, to apply a strategy to determine the burial dose used in the final age calculation. Evidence of age overestimation owing to partial bleaching has been shown by measuring resetting rates as a function of attenuation of light in water, for example, in varied turbidity or transport distance; dating samples with independent age control; and dating modern samples (see Wallinga 2002; Jain et al. 2004 and references therein). Analytical approaches to identifying partial bleaching include examining the scatter in D_e distributions, comparing the form of different components of decay curves to isolate the most sensitive and well-bleached portion of luminescence signals, and comparing different luminescence signals, for example, by comparing TL and OSL results from a single sample (see Wallinga 2002 and references therein) or by comparing the differential bleaching rates of quartz and feldspar (Murray et al. 2012).

Approaches to determining the burial age from a population of D_e from a sample that has experienced partial bleaching include using small aliquots or single grains to isolate and disregard the partially and/or unbleached portion of the population of D_e and the application a variety of statistical methods (see Wallinga 2002; Rittenour 2008 and references therein). While using single grain aliquots is often the preferred method to cope with partially bleached samples, the use of small aliquots is statistically viable and more efficient in many situations. The luminescence signal from individual grains is highly variable, and in multiple grain aliquots of quartz, 90–95 % of the total light emitted originates from only 5–10 % of the grains (Duller et al. 2000; Jacobs et al. 2003). In those cases, small aliquots of < 100 grains are statistically equivalent to the single grain approach and improve the efficiency of analysis (Duller 2008). One approach is to test a small number single grains (e.g., one disk of 100 grains) to determine the percentage of grains that produce a luminescence signal and then adjust the number of grains per aliquot (i.e., the size of the aliquot) accordingly (e.g., Rodnight et al. 2006).

The use of single grains or small aliquots is particularly important for young samples (< 1 ka), and Jain et al. (2004) suggest that age offsets associated with partial bleaching are sufficiently masked by the analytical uncertainty associated with older samples. Nonetheless, heterogeneous bleaching has been observed in fluvial samples > 1 ka (e.g., Folz et al. 2001; Thomas et al. 2005; Brook et al. 2006; Srivastava et al. 2006; Eitel et al. 2006; Rodnight et al. 2006; Keen-Zebert et al. 2013), and disregarding the heterogeneously bleached condition can result in age overestimation greater than analytical error. Regardless of the expected age, an assessment of the degree of bleaching should be conducted taking into account the characteristics particular to each sample and site.

Samples with heterogeneous bleaching tend to have D_e populations with a wide range (high over-dispersion). Several statistical approaches to estimating burial doses have been posed including calculating the mean of the lowest 5–10 % of population of D_e (Olley et al. 1998), fitting the “leading edge” of the distribution after scatter from experimental errors is removed (Lepper et al. 2000), and fitting the distribution of D_e to statistical models such as the minimum age model (MAM) or finite mixture model (FMM) (Gailbraith et al. 1999; Galbraith 2005). For widely ranging, complex, multimodal distributions of D_e , for example, arising from fluvial sediment sources of mixed age, F-ratio filtering (a ratio of two independent estimates of the variance in a normal distribution) can be applied to discriminate between discrete populations within a distribution (Spencer et al. 2003; Spencer and Robinson 2008). In some partially bleached sedimentary environments, ages of samples in vertical succession may overlap owing to high over-dispersion and error. In these kinds of cases, rather than define a single age for a sample, it may be advantageous to define a probability distribution of ages from the population of D_e using a bootstrapping approach that enables the identification of trends in sedimentation rates down-

profile (Cunningham and Wallinga 2012). The choice of statistical approach to modeling the burial dose should be made according to the characteristics of the site, considering factors that contribute to large dispersion in the population of D_e such as partial bleaching, uneven dosimetry, and post-depositional mixing, for example, owing to bioturbation and other soil forming processes. Though inputting a smaller number of replicates of D_e into statistical models may be satisfactory for Gaussian distributions, for more complex distributions, such as those exhibiting high over-dispersion, at least 50–60 acceptable replicates of D_e may be necessary to generate reproducible results (Rodnight 2008; Woda and Fuchs 2008).

Current Gaps in Knowledge Related to Fluvial Processes

Early assumptions held that because fine grains are transported higher in the water column, they should be better bleached than coarser grains; however, studies have shown that coarser grains tend to be better bleached (Olley et al. 1998; Truelsen and Wallinga 2003; Hu et al. 2010). Although thermal transfer may be impacted by grain size, Truelsen and Wallinga (2003) suggest that better bleaching of coarse grains is not an artifact of thermal transfer effects related to grain size. Some possible explanations for this phenomenon include (1) channel bed armoring at lower flows or during receding flood flows in which finer sediments work into pore spaces in the bed through kinematic sorting leaving a coarser layer on top of the channel bed that would be exposed to sunlight during lower base flows; (2) for rivers with flashy and/or perennial flows, which are common in dryland rivers, equal mobility of all grain sizes during floods which would result in equal exposure to sunlight; (3) overbank sand dunes being deposited on the floodplain that are well exposed to sunlight then buried in subsequent flows; (4) fine sediment being transported as flocs (larger aggregates of fine sediment) the interiors of which would not be exposed to light during transport; and (5) in basins with heterogeneous lithology, differences in the source rock of fine and coarse fractions may give rise to fundamental differences in luminescence behavior or characteristics. These processes do not occur in all rivers, and other fluvial processes may contribute to a relationship between grain size and bleaching, but this phenomenon remains untested and more applications of luminescence could yield insight into fundamental fluvial processes related to grain size and transport.

Other issues associated with grain size and dating fluvial sediments relate to sorting, or the mixture of grain sizes within a landform or sample. Potential problems related to poor sorting (large variation of grain sizes within a feature) involve both the high potential for partial bleaching and uneven dosimetry, for example, from mixed fine, sand, gravel, and cobble sizes within a single feature such as a gravel bar. Outside of the findings of Murray et al. (1995) that floodplain deposits are better bleached than channel deposits, observations of the impact of sorting on luminescence ages are lacking.

A relationship between better bleaching with greater transport distance has been observed in some studies (Stokes et al. 2001; Pietsch et al. 2008; Summa-Nelson and Rittenour 2012). Though the phenomenon has not been thoroughly investigated in a variety of settings, possible explanations include increased sorting downstream, modification of grains during transport, and increased sensitivity owing to repeated bleaching and dosing cycles following detachment from the parent material through erosion and redeposition of sediment. More work is needed to validate these observations in other fluvial systems.

Some basic understanding about fluvial processes may be discovered through the use of portable OSL readers even though they are currently limited to measuring photon counts and do not enable

age determination. In particular, where multiple samples are collected across a gradient, insight on sedimentary characteristics may be discovered. For example, changes in sedimentological processes, variation in provenance, the likelihood of post-depositional mixing, and the suitability of sediments to dating with OSL can be assessed with photon counts from portable OSL readers (Muñoz-Salinas et al [2011](#)).

Recent Applications of Luminescence to Dating Fluvial Sediments That Have Independent Age Control

Historical and Sedimentary Age Controls

For case studies using historical information sedimentary stratigraphy, and radiocarbon as independent age controls, only publications that postdate Rittenour's review ([2008](#)) are presented here. On terraces on the Middle Thames with a chronology well-constrained by OSL, U/Th, and TL on artifacts, Pawley et al. ([2010](#)) found good comparison of quartz OSL with the expected 450 ka age of the site. Initial results found systematic underestimation of 10 % owing to contamination of the OSL signal by a thermally unstable medium component. The fast component was isolated by curve fitting and by early subtraction of the background, the latter of which was found to provide the best separation of the thermally unstable signal. For historical fluvial deposits on the Danube and Ebro, Fiebig et al. ([2009](#)) used 2 mm aliquots and the finite mixture model (FMM) on partially bleached sediments to find young ages (< 500 a) that were stratigraphically consistent and agreed with well-constrained chronologies from dendrochronology and archaeology at the site. In the hyperarid Negev, Porat et al. ([2010](#)) used the minimum age model on partially bleached sediments just underlying the abandoned surface of an alluvial fan and found good agreement between OSL and soil age estimates, morphostratigraphy, and well-dated lacustrine shorelines for the age of fan abandonment.

Radiocarbon

Because the applicable age range of luminescence overlaps that of radiocarbon, results from the two techniques are often used to validate each other. In comparing radiocarbon with OSL results and stratigraphic position in Holocene arroyo sediments in southern Utah, Summa-Nelson and Rittenour ([2012](#)) used both single grain and small aliquots of quartz to determine D_e distributions and the minimum age model to determine the burial dose used to calculate the age. They find good agreement within errors between OSL and radiocarbon results except for one sample that had no positive skew and low over-dispersion, and they suggest therefore that there was a problem with the dose rate estimation rather than with the determination of D_e . Very small aliquots (0.3 mm) were used with success by Cheetham et al. ([2010b](#)) to complete a Holocene alluvial chronology in southeastern Australia. Radiocarbon and OSL results were chronostratigraphically consistent, but for a few samples, evidence of bioturbation resulted in poor results from both techniques (Cheetham et al. [2010b](#)). Compared to the larger aliquots used by Cheetham et al. ([2010a](#)), results from the small aliquots used by Cheetham et al. ([2010b](#)) were more accurate, but were within two standard deviations of the earlier measurements of larger aliquots. Briant and Bateman ([2009](#)) conducted a cross-comparison of paired OSL and radiocarbon samples of fluvial sediments of the Nene and Welland rivers in eastern England and reconfirmed results of an earlier study (Briant et al. [2004a, b, 2005](#)) that had found offsets between OSL and radiocarbon results in older samples. In the later study, dose recovery tests and the SAR protocol were used on small (2 mm) aliquots to improve the confidence in the results of the earlier study that had used large aliquots, bringing into

question the possibility of partial bleaching. Reconfirming Briant et al. (2004a, b, 2005), the results show good age agreement between OSL and radiocarbon ages before 35 ^{14}C ka BP, but age underestimates by radiocarbon later (Briant and Bateman 2009). The authors attribute the result to the contamination of older organic material with modern carbon and suggest that confidence in conventionally pretreated radiocarbon ages be limited to < 35 ^{14}C ka BP.

Cosmogenic Radionuclides

Owen et al. (2006) and DeLong and Arnold (2007) compared OSL ages of alluvial sediments within fans to ^{10}Be cosmogenic radionuclide (CRN) exposure ages of boulders that were partially buried in alluvial fan surfaces. Both studies find good stratigraphic agreement among the methods, but acknowledge scatter in the CRN results owing to inheritance, post-depositional erosion and weathering, a limited number of CRN samples, and/or shielding. Hetzel et al. (2004) and Nissen et al. (2009) directly compared depth averaged ^{10}Be CRN ages to OSL ages of sediments within alluvial fans and found that OSL underestimated the ages, citing feldspar contamination and abnormal quartz characteristics. However, because the signal resetting mechanisms are fundamentally different (OSL being reset by exposure to light or heat and cosmogenic depth profiles being reset by a number of processes including sediment mixing, deep surface truncation, and inheritance), direct comparison of OSL and CRN ages is somewhat questionable (Guralnik et al. 2011). To cope with this discrepancy in resetting mechanisms, Guralnik et al. (2011) fit cosmogenic and luminescence data to a model that utilizes both OSL and CRN data to provide a more nuanced platform for interpretation of alluvial terrace history than is possible with results from one technique or from directly comparing both techniques on single sample sites.

Summary

Luminescence techniques can be used to date fluvial sediments for a variety of applications from understanding fluvial processes and alluvial stratigraphy to dating other landscape features. The high potential for partial bleaching prior to burial is the main concern regarding the accuracy and precision of luminescence ages of fluvial sediments. However, a combination of small aliquot or single grain techniques and the use of appropriate statistical models have yielded successful age determination of fluvial sediments with luminescence. Independent age dating techniques including historical ages, radiocarbon, and CRNs has repeatedly validated luminescence ages of fluvial sediments in a wide age range environmental settings and ages from the modern to the Pleistocene.

Luminescence, Colluvial Sediments

Andreas Lang*

School of Environmental Sciences, University of Liverpool, Liverpool, UK

Definition

Colluvium: sediment eroded from and transported along hillslopes by water, gravity, or human action and usually forms a wedge-shaped sediment body at the footslope.

Hillslope deposits are important sedimentary archives for geomorphological, paleoenvironmental, and increasingly also archaeological research. Besides others, they are utilized for reconstructing landscape response to climate change (e.g., Hanson et al. 2004), anthropogenic-induced soil erosion (e.g., Lang 2003), and fault activities (e.g., Fattahi et al. 2006). Various definitions for the term colluvium are in use in different scientific communities. In general, the term describes sediments that are eroded from and transported along hillslopes by running water or gravity and that usually form wedge-shaped deposits on the footslope. Typically, colluvial sediments are formed through processes on slopes that are spatially diffusive and are distinguished from alluvial sediments, which are transported across slopes in spatially confined channels to form alluvial fans and cones. The recent research focus on colluvial systems is linked to the limited transport distance within such systems and their reduced complexity that often allows cause-consequence analyses of sediment formation.

Luminescence dating determines the time when sediments were formed if sufficient exposure to daylight (bleaching) immediately before burial occurred. The potential of using luminescence for dating colluvium has already been explored by Forman et al. (1991) using thermoluminescence (TL). Wintle et al. (1993) were the first to report successful infrared-stimulated luminescence (IRSL) dating of colluvial sediments; later also optically stimulated luminescence (OSL) has been utilized for dating colluvium (e.g., Fuchs et al. 2004). For luminescence dating of colluvial sediments, limitations exist that are related to (i) limited bleaching due to limited exposure of sediment grains to daylight during the short and often rapid transport of slope deposits and (ii) low-luminescence sensitivity of quartz in many lithologically immature deposits:

1. Several processes are involved in eroding and transporting sediment along slopes, like sheet, rill and gully erosion, mass movements (e.g., debris flows, sliding, falling), and soil creep (e.g., solifluction). While these processes act on hillslope material to move it downslope, the sediment itself may move as a rigid block as in the case of sliding. Thus, in respect of exposure to daylight, only a small fraction of sediment grains involved in the process (e.g., only the outside layer of sediment grains on a rigid block) may be exposed to daylight. If material is transported in suspension, the intensity and spectral composition of the daylight is subdued by the suspended load. Also, many high-magnitude slope processes erode the material that they are moving across and incorporate unbleached material from the subsurface in the colluvial deposit they leave behind.

*Email: lang@liverpool.ac.uk

Catchment morphology and erosion process constrain the sediment pathway, sediment travel distance, and sediment sink. Because travel distance is usually rather short, the probability of efficient bleaching is reduced and events may occur fully during unfavorable daylight conditions (e.g., transport entirely at night). In addition, a large variety of sediment source materials exist, leading to a large variety in sediment characteristics, e.g., grain-size distribution, mineral composition, or organic content. Some of these sediments tend to be transported as single mineral grains, like well-sorted dry sand, while others are prone to coagulation, like clay-dominated sediments. The latter often hampers sufficient zeroing of the luminescence signal, because the inner grains of an aggregate are shielded from daylight exposure (Lang 1994). The same may result from mineral coatings, where, e.g., iron, manganese, or carbonate coatings hamper the daylight to penetrate into the mineral grains.

2. As in other sedimentary environments, the use of quartz OSL in colluvial deposits can be hampered by poor luminescence sensitivity. Often materials incorporated in colluvium are freshly eroded from bedrock and enter the erosion-transport-deposition cycle for the first time. Quartz from such environments usually displays rather low-luminescence sensitivity as that seems to increase only after repeated cycles of sediment recycling (Pietsch et al. 2008).

Despite the shortcomings, there are many examples where luminescence dating of colluvium has successfully been carried out (for reviews, see Lang 2003; Fuchs and Lang 2009). Two factors influence this: (a) hillslope sediments are often eroded, transported, and accumulated not in a single event but temporary storage on the hillslope occurs, before a further mobilization takes place (e.g., Lang and Hönscheidt 1999). This increases the probability of exposure to daylight and thus bleaching. (b) Bioturbation and mechanical processes in the soil as well as cultivation allow that mineral grains are frequently exposed to daylight before the sediment grains are eroded. In many cases exposure to daylight continues after deposition until the sediment grains are covered through further sedimentation. According to Berger and Mahaney (1990), this process is more important for sediment bleaching than the colluvial transport itself. Nevertheless, as in other sedimentary environments, detecting and excluding insufficient bleaching is a necessary prerequisite for successful luminescence dating of colluvial sediments. This is demonstrated by some investigations of modern colluvial sediments, where residual luminescence signals were identified, which would result in age overestimations of hundreds (Yanchou et al. 2002) or even thousands of years (Porat et al. 2001). The large variety of sedimentary process and regional and climatic settings, however, make generic statements difficult: single-grain dose distributions by Vandenberghe et al. (2009) derived from fault scarp colluvium are unimodal, rather narrow, and are only slightly skewed, indicative of sufficient bleaching which is also confirmed by comparing the resulting OSL ages with independent age information. Porat et al. (2009) use OSL to date colluvial sediments from Eilat, southern Israel. Based on single-grain OSL measurements of quartz, they are able to identify bleached grains and manage to establish a chronology spanning the interval 1,300 years to 500 years ago. As in other sedimentary environments, and where possible, the analyses of dose distributions of single grains and small aliquots seem crucial also in colluvial deposits.

Conclusions

Due to rather restricted bleaching possibilities, colluvial sediments are challenging for OSL dating. Issuing generic statements on the suitability is difficult as colluvial sediments exist in a great variety in very different environments. It has been demonstrated that OSL dating is possible in

many cases; but success is often difficult to judge and success at one location does not guarantee success elsewhere. To establish a trustworthy and robust OSL chronology, internal (e.g., stratigraphic integrity) and external (e.g., accordance with independent information) consistency is a requirement.

Fission Track Dating and Thermochronology

Andrew JW Gleadow* and Christian Seiler
School of Earth Sciences, University of Melbourne, Melbourne, VIC, Australia

Definitions

Fission Track	A linear trail of radiation damage in an insulating solid resulting from the passage of fission fragments formed by spontaneous or induced fission of a heavy nucleus, especially of isotopes of uranium.
Fission Track Dating	A technique for geological or archaeological dating based on the accumulation of fission tracks from the spontaneous nuclear fission of ^{238}U in natural minerals and glasses.
Fission Track Density	The number of fission tracks counted per unit area on a given surface.
Fission Track Length	The length of a fission track measured under a microscope after chemical enlargement.
Fission Track Annealing	The property of fission tracks that results in the gradual repair of the radiation damage in the host material upon exposure to elevated temperatures.
Fission Track Analysis	The measurement of different fission track parameters including track density and track length that are used to monitor the degree of fission track annealing for the purpose of reconstructing rock thermal histories.
Fission Track Thermochronology	The reconstruction of rock thermal histories based on the fission track annealing properties of one or more constituent minerals.

Introduction

The use of accumulated radiation damage tracks from spontaneous nuclear fission in natural minerals was first suggested more than 50 years ago as the basis for a geological dating technique by Price and Walker (1963). Since that time fission track analysis has evolved to serve a range of geological, and occasionally archaeological, dating applications, with particularly widespread utility in the field of thermochronology. In this approach, the unique characteristic of fission tracks to fade, or anneal, at elevated temperatures is used to obtain both time and temperature information. The development of powerful modelling techniques now allows for reconstruction of the thermal histories of rocks by analysis of fission tracks in their constituent minerals. Fission track analysis has therefore emerged as one of the most important methods for thermochronology, especially in the low-temperature ($<150\text{ }^{\circ}\text{C}$) environment characteristic of approximately the upper 5 km of the Earth's crust.

Fission tracks were first observed by transmission electron microscopy as linear trails of radiation damage in mica by Silk and Barnes (1959) and Price and Walker (1962). These tracks appeared as cylindrical regions of highly disordered or amorphous material averaging around 10 nm across within an undisturbed crystalline matrix. Price and Walker (1963) went on to show that these tracks

*Email: gleadow@unimelb.edu.au

could be enlarged by a simple chemical etching treatment so that they could then be observed much more conveniently under an optical microscope. They also showed that many natural micas had a background of tracks from the spontaneous fission of ^{238}U and suggested that this was the basis for a new geological dating method. The simplicity of revealing fission tracks by etching led to a rapid expansion of activity by many researchers that explored the application of fission tracks, and other nuclear particle tracks, in many different branches of science as summarized by Fleischer et al. (1975). Of these, fission track dating has proved to be by far the most important.

Early work on fission track dating showed that fission tracks could be observed in a variety of natural minerals and glasses (for a review, see Wagner and Van den haute 1992), but most of these contain insufficient uranium or are too rare to be useful in routine dating studies. The pioneering studies by Naeser (1967) and Wagner (1968) focused attention on commonly occurring, uranium-bearing accessory minerals such as apatite, titanite, and zircon. These accessory minerals occur as trace constituents in a wide variety of common igneous, metamorphic, and sedimentary rocks and mostly contain suitable amounts of uranium within their structures (typically in the ppm to hundreds of ppm range) to be useful for fission track dating. Of these minerals, just one, apatite, has come to account for more than 80 % of all fission track analyses because of its common occurrence, generally suitable uranium concentration, consistent etching properties, and well-understood thermal annealing behavior.

The use of a particular mineral for fission track dating requires estimates of three quantities: (1) the number of fission tracks in the material, (2) the amount of fissionable parent isotope present, and (3) the rate of spontaneous fission decay. In addition, it must either be assumed that no fission tracks have been lost since the system was formed or that the degree of loss can be estimated. It was soon recognized, however, that fission tracks could undergo annealing if exposed to elevated temperatures, resulting in fission track ages that were “too young” compared to independent formation age estimates. Considerable effort was therefore devoted to understanding and quantifying this fission track annealing process, initially with the objective of “correcting” the observed ages in order to recover the true age of the material. Such attempts resulted in some success, particularly in dating natural glasses, such as tektites (Storzer and Wagner 1969).

It was soon realized, however, that this concept could be turned around so that fission track annealing could be used to recover information about the conditions of annealing rather than being used to correct ages. The three American physicists who originated the fission track method, Fleischer et al. (1965a, p. 389), observed: “As in all age measurements, one must ask what time interval is being measured. It is our opinion that the “low” ages which are sometimes obtained by the fission-track method represent definite physical events, such as heating episodes.” This was one of the key insights that initiated the study of thermochronology – the use of temperature-sensitive dating methods to reconstruct rock thermal histories – a field that has come to dominate the use of fission track analysis over the last 30 years.

The basic principles and applications of fission track dating and thermochronology have been extensively reviewed by Wagner and Van den haute (1992), Gallagher et al. (1998), Gleadow et al. (2002), Donelick et al. (2005), and Tagami and O’Sullivan (2005).

Spontaneous Fission and Nuclear Track Formation

Spontaneous nuclear fission is one of the rarest forms of radioactive decay and occurs naturally only in the isotopes of uranium and thorium. In practice, however, only ^{238}U is responsible for the fission tracks observed in natural materials, for which the spontaneous fission half-life is approximately

8×10^{15} years. Other isotopes of these heavy elements, ^{235}U and ^{232}Th , can effectively be ignored as a source of fission tracks because they are either much less abundant or have significantly longer half-lives. Even in ^{238}U , the rate of spontaneous fission decay is vastly slower than the normal alpha decay mode, so that only about one in every two million decay events in this isotope is the result of nuclear fission. The much more common alpha decay is the basis for three other dating methods (see “► [Uranium–Lead, U-Series, and U–Th:He Dating](#)”).

Spontaneous fission results in a great variety of middle-weight isotopes as daughter products, most of which are extremely difficult to measure due to the rarity of these decay events. However, fission track dating is extremely sensitive as it measures the *effect* of the decay in the form of radiation damage, rather than the decay products themselves. Each fission track represents a single ^{238}U nucleus that has decayed in this way, so that counting fission tracks is equivalent to counting individual radioactive decay events.

In spontaneous fission the parent ^{238}U nucleus splits apart into two sub-equal and massively charged particles that carry away most of the enormous energy released by nuclear fission as kinetic energy. These massively ionizing particles travel rapidly apart at 180° to each other, to produce a single linear trail of radiation damage in the host material, the fission track (see “► [Radiation Defect](#)”). The result is a narrow track core of amorphous material about 5–10 nm across but continuing for lengths of up to 20 μm in some materials. In apatite, recent evidence suggests that the track core may even be a void (Li et al. 2012).

Revealing and Observing Fission Tracks

Fission Track Etching

Fission tracks are revealed for counting and measurement under a microscope by a chemical etching procedure. The etchant preferentially attacks the damaged core of the track, which is chemically more reactive than the surrounding undamaged matrix. This contrast in reactivity is to be expected in crystalline minerals but also exists to a lesser degree in natural glasses, where the track core is more disordered than the surrounding glass matrix.

Etching is typically carried out on an internal surface of the material to be dated. Internal surfaces are exposed either by grinding and polishing or by exploiting the natural cleavage of minerals such as mica. The surface is immersed in a suitable chemical etchant for the particular mineral to enlarge latent fission tracks to optical dimensions of $\sim 1\text{--}2\ \mu\text{m}$ across.

Initially, etching of the track core is controlled by the radiation damage itself, but further enlargement of the track is controlled by the properties of the material. In the case of etching tracks in glasses, the rate of etching along the track is only slightly faster than the bulk etching rate of the surrounding material, so that the track is simultaneously widening while the etchant is still penetrating toward the end of the track. The outcome is a broad, conical-shaped track. In minerals, the etchant penetrates almost instantaneously along the whole length, so that the track subsequently widens as a nearly parallel-sided hole. As the etching rates are not uniform in different crystallographic directions, fully etched tracks are essentially faceted “negative crystals” forming shapes like knife blades, daggers, prisms, and pyramids depending on their orientation (Fig. 1). Figure 2 shows the appearance of well-etched tracks on a c-axis-parallel surface in an apatite crystal.

Prior to etching, minerals are typically separated from their host rock by crushing and then using standard heavy liquid and magnetic separation techniques, before mounting the concentrated mineral grains in a suitable medium such as epoxy resin or, for use with highly reactive etchants, transparent FEP teflon. Some typical etching treatments for different materials are listed in Table 1.

Fig. 1 The shape of etched fission tracks on different crystal surfaces in apatite (a). The scanning electron microscope image (b) shows the elongated appearance of etched fission track openings on a surface parallel to the c-axis. The long and short axes of etch pits are known as D_{par} and D_{per} (Donelick et al. 2005)

Fig. 2 Etched spontaneous fission tracks in an apatite grain from the Grassy Granodiorite, King Island, in southeastern Australia. The tracks appear as dark, randomly oriented lines of up to about 15 μm length. Faint lines running continuously across the surface are etched polishing scratches

Table 1 Commonly used etching conditions for revealing fission tracks

Mineral	Etchant	Temperature	Time
Apatite	5 N HNO_3	20 $^{\circ}\text{C}$	20 s
Zircon	KOH:NaOH eutectic	220 $^{\circ}\text{C}$	4–100 h
Titanite	50 N NaOH	120 $^{\circ}\text{C}$	30 min–5 h
	1HF:2HCl:3HNO ₃ :6H ₂ O	20 $^{\circ}\text{C}$	1–25 min
Muscovite mica	HF (40 %)	20 $^{\circ}\text{C}$	20 min
Natural glasses	HF (48–15 %)	20 $^{\circ}\text{C}$	15 s–5 min

Fission Track Microscopy

Observation and measurement of fission tracks requires a high-quality research microscope typically configured for illumination by both transmitted and incident light, a rotating nosepiece with various objectives up to $100\times$ with an appropriate substage condenser and a motorized x-y scanning stage. Track lengths are conventionally measured using a drawing tube device that superimposes an image of a digitizing tablet on the visible image, although modern equipment generally uses digital cameras attached to the microscope for this purpose (see section “[Automation of Fission Track Measurements](#)”).

The choice of objectives is important for fission track analysis and all objectives should be corrected for slides with no cover glass. Most researchers prefer to use dry objectives, rather than oil immersion lenses, especially for observation of fission tracks in apatite and mica whose refractive indices are almost the same as the immersion oil making the tracks difficult to see. Oil immersion lenses are, however, sometimes used for observing tracks in higher refractive index minerals, such as zircon and titanite.

The number of fission tracks present on a particular surface is most commonly counted at a magnification of $1,000\times$ or more by scanning across a calibrated grid of known area in the microscope eyepiece and recording the number of tracks with a hand tally device. In modern systems, digital cameras attached to the microscope generate a calibrated live image that can be analyzed directly on a computer, allowing counting of more complex regions of interest and marking of tracks on screen using a computer mouse. Digital image analysis may also be used as discussed below (see section “[Automation of Fission Track Measurements](#)”).

Fission Track Measurements

Measurements of fission tracks fall into two categories – counting the number of etched fission tracks intersecting a prepared surface and measuring various dimensions of the etched tracks. These two types of measurements respectively contain the time and the temperature components that are required for thermal history reconstruction.

Track Counting

The primary parameter measured in fission track analysis is the track density, which provides an estimate for the number of fission events accumulated over time in a geological material. The fission track density is defined as the number of track intersections per unit area of a given surface, usually expressed as tracks per cm^2 . As such, the track density is a two-dimensional measurement, which is related to the three-dimensional distribution of fission events via the average length of the fission tracks in that material.

Due to the anisotropic etching properties of minerals (see section “[Fission Track Etching](#)”), track densities are usually measured on specific crystal planes. In apatite and in zircon, the optimum surfaces for counting fission tracks are those that are cut parallel to the crystallographic c-axis. Such surfaces reveal tracks with a well-developed form and a high detection efficiency, which may be defined as the number of tracks actually counted as a function of the total number of tracks crossing that surface. In mica the optimum surface is the basal cleavage plane.

Track densities are of two kinds, spontaneous and induced. Spontaneous, or fossil, track densities record the number of tracks originating from spontaneous fission of ^{238}U contained within the target material. These are the fission tracks that accumulate over the geological lifetime of the material, their number being proportional to the time over which that accumulation has been taking place, and

the uranium concentration. Induced track densities, on the other hand, record the number of tracks arising from neutron-induced fission of ^{235}U and are used during fission track dating as a proxy for the amount of ^{238}U present in a sample (see section “[Fission Track Methods](#)”).

In determining the track density, it is important to reliably discriminate true fission tracks from non-track features such as dislocations, etching artifacts, inclusions, surface dust, and scratches. In most cases, the tracks are obvious and discrimination is straightforward, but occasionally very difficult grains with complex dislocation swarms are encountered. Such grains are best avoided altogether. Three commonly used criteria to discriminate tracks from non-track features are as follows: Fission tracks are straight-line defects, are randomly oriented, and are of limited length, determined by the range of fission fragments in that particular material (Fleischer and Price 1964). Dislocations and other spurious etch pits, on the other hand, are often preferentially oriented in parallel arrays, may be much longer than fission tracks, and often show complex curvature and branching paths. Interference from some of the other artifacts can be minimized by clean handling and careful observation.

Track Length Measurements

A second group of measurements relates to the overall dimensions of fission tracks, which can give valuable information on the degree of thermal annealing they have experienced. Different dimension parameters that have been used include the diameter of track etch pits in glasses, the projected lengths of tracks in minerals (the apparent length of dipping tracks projected onto the horizontal surface), and the lengths of confined fission tracks.

Most fission track studies in minerals since the mid-1980s have measured the lengths of horizontal confined tracks, especially in apatite (Gleadow et al. 1986). Confined fission tracks are tracks with their entire etchable length contained within the body of the surrounding mineral. In this case, the etchant penetrates into the confined track, not directly from the surface but from a surface-intersecting track or fracture. Depending on the way they are etched, confined tracks can be either track-in-track events (TINTs) or track-in-cleavage events (TINCLEs, Lal et al. 1969) as illustrated in Fig. 3. TINTs are now favored over TINCLEs, because the latter introduce additional observational biases and may be anomalously stabilized (e.g., Barbarand et al. 2003), making their lengths unrepresentative of the thermal history. The orientations of these tracks relative to the crystallographic c-axis are also usually measured to account for differences in both etching and annealing characteristics of tracks in different orientations. Confined tracks show the closest approximation to the true lengths of unetched fission tracks, although their measurement is still subject to various unavoidable, but well-understood, sampling biases (Galbraith 2005).

Due to the limited accuracy of vertical movement in earlier-generation microscopes, measurements are usually made only for *horizontal* confined track lengths, thereby avoiding the need to correct for track inclination (Laslett et al. 1982). Modern microscopes have overcome this problem, so that it is now possible to accurately measure confined tracks of any orientation, which obviously increases the sampling size. Typically the lengths of around 100 confined track lengths are measured, although this may not be possible in samples with low track densities.

The number of TINTs in a particular sample can be enhanced by implanting artificial fission tracks from a ^{252}Cf source (Donelick and Miller 1991). This increases the number of etch channels to maximize the likelihood of TINT intersections below the surface and is especially useful where too few confined tracks can be found naturally.

Fig. 3 Photomicrographs of confined fission tracks in apatite in reflected (*left*) and transmitted light (*right*). Two track-in-track (*TINT*) features are highlighted by arrows in (a) and (b), and two track-in-cleavage (*TINCLE*) features in (c) and (d). The dashed arrows show the crystallographic c-axis direction defined by the elongation of the surface track etch pits in reflected light

Track Diameter Measurements

Measurements of track diameters were first used in natural tektite glasses as a means for correcting the apparent fission track ages for partial loss, or fading, of the spontaneous tracks (e.g., Storzer and Wagner 1969; see “► [Impact Glass \(Fission Tracks\)](#)”). This followed the observation that etched diameters of spontaneous tracks were smaller than induced tracks, and experiments revealed a relationship between the reduction in track diameter and the track density. Although his approach worked well for glasses, a similar approach for minerals was much less successful as corrected ages rarely relate to the formation age of the host sample.

Fission track fading or annealing in apatites is influenced by their chemical composition (see section “[Experimental Fission Track Annealing Studies](#)”), primarily variations in chlorine concentration (Green et al. 1985). The rate of etching is also observed to vary with composition in apatite, such that the tracks appear more strongly etched in some cases than others after constant etching. Measuring track diameter parameters such as D_{par} and D_{per} – the average diameters of etch pits parallel and perpendicular to the crystallographic c-axis, respectively (Fig. 1) – can thus be used to indirectly monitor the annealing sensitivity of apatite (Donelick et al. 2005). D_{par} values typically vary between about 1.2 and 3.5 μm across the range of natural apatite samples. Although there is a coarse correlation between D_{par} and chlorine content of different apatites (Donelick et al. 2005), this relationship becomes less clear for the most common fluorine-rich varieties of apatite (e.g., Green et al. 2005) leading to some debate about the usefulness of D_{par} alone to monitor track annealing.

Fig. 4 Automated counting of fission tracks by *coincidence mapping*. The procedure digitally combines a slightly defocused transmitted light image (**a**) and a focused reflected light image (**b**) of the same tracks to obtain the overlapping features shown as black spots in (**c**), which are then analyzed automatically to obtain the number of tracks, discriminate track overlaps, and determine dimensions such as D_{par}

Automation of Fission Track Measurements

The latest generation of fully motorized digital research microscopes allows for comprehensive computer control of all aspects of microscopy and the acquisition of high-quality digital images. This new technology has converged with rapid increases in computing power and cheap availability of abundant digital image storage to bring new opportunities for automation to the laborious process of fission track data collection.

Gleadow et al. (2009) have described a procedure that makes use of these new technologies to implement autonomous digital imaging and automatic counting of fission tracks using image analysis. The emphasis has been on counting tracks in apatite and mica to support the great bulk of fission track analysis conducted today, but the system is readily adaptable to other minerals, glasses, and plastic track detectors. The central procedure of *coincidence mapping* relies on the digital comparison of pairs of reflected and transmitted light images for each microscopic field of view, as illustrated schematically in Fig. 4. A detailed Z-stack of transmitted light images is also captured at the same location to provide a fully focusable image of each grain for later inspection. The system also includes a comprehensive set of partially automated tools for locating suitably oriented grains in the mount as well as measuring various geometric parameters, including c-axis orientation, track length, and orientation, and D_{par} .

Methods of Dating

Fission Track Methods

As in any radiometric dating method, determining a fission track age involves obtaining a measure of both the parent isotope and the daughter products of the decay scheme. In this case, the number of decay events (daughter products) is measured using the spontaneous track density as described in

section “[Track Counting](#).” The parent isotope, ^{238}U , is normally estimated indirectly by using ^{235}U as a proxy, the concentration of which is obtained by counting the number of induced fission tracks produced during thermal neutron irradiation (see section “[Track Counting](#)”). Induced tracks are related to the ^{238}U concentration via the known $^{235}\text{U}/^{238}\text{U}$ ratio, which can be taken as constant (0.73 %) in natural geological materials, and the total neutron fluence received.

Most fission track dating techniques, therefore, require determination of the ratio of spontaneous to induced track densities in a sample and measurement of the neutron fluence received. There are a number of ways in which these variables can be determined (Gleadow 1981; Hurford and Green 1982; Wagner and Van den haute 1992; Gleadow et al. 2002). In *grain-population* methods, both spontaneous and induced track densities are determined as averages over a large number of mineral grains from different aliquots, while *grain-by-grain* methods allow individual ages to be determined for each analyzed mineral grain. Since the 1980s, just one of the grain-by-grain methods, the external detector method (EDM, see section “[The External Detector Method](#)”), has become standard practice for the great majority of mineral dating studies due to its analytical convenience and the individual grain data that are acquired.

An important recent development is the emergence of laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) as routine tool for the precise analysis of trace elements in minerals. This method can measure the concentration of the parent isotope ^{238}U directly, rather than via ^{235}U , thereby eliminating the need for neutron irradiation while maintaining many of the benefits of the EDM method (see section “[The Laser Ablation ICP-MS Method](#)”).

The Fission Track Age Equation and Calibration

The fission track age equation is a specialized form of the general radiometric age equation that expresses the fission track age (t in years) in terms of the ratio of the spontaneous fission track density ($\rho_s \text{ cm}^{-2}$) to the induced track density ($\rho_i \text{ cm}^{-2}$) as follows (Fleischer and Price 1964; Naeser 1967):

$$t = \frac{1}{\lambda_D} \ln \left(1 + \frac{\lambda_D \phi \sigma I \rho_s}{\lambda_f \rho_i} \right) \quad (1)$$

where

- λ_D = total decay constant for ^{238}U ($1.55125 \times 10^{-10} \text{ year}^{-1}$)
- λ_f = spontaneous fission decay constant of ^{238}U ($8.46 \times 10^{-17} \text{ year}^{-1}$)
- I = isotopic ratio $^{235}\text{U}/^{238}\text{U}$ (7.2527×10^{-3})
- σ = thermal neutron cross section for ^{235}U ($580.2 \times 10^{-24} \text{ cm}^{-2}$)
- ϕ = thermal neutron fluence (n cm^{-2})

A calibration factor g must be introduced if the spontaneous and induced tracks are measured on surfaces with different track registration geometries (spherical or half-spherical; see section “[The External Detector Method](#)”) and detection efficiencies, as is the case in the external detector method.

For methods that require neutron dosimetry, the neutron fluence is calculated from the following:

$$\phi = B \rho_d \quad (2)$$

where ρ_d is the induced track density measured in a mica external detector that was in contact with a uranium-bearing standard glass in the same irradiation package. The constant B is calibrated by comparison with independent thermal neutron fluence dosimetry.

Substituting Eq. (2) into Eq. (1) gives the general working form of the fission track age equation expressed in terms of the three track densities:

$$t = \frac{1}{\lambda_D} \ln \left(1 + \lambda_D \zeta g \frac{\rho_s}{\rho_i} \rho_d \right) \quad (3)$$

where

$$\zeta = \frac{\sigma I B}{\lambda_f} \quad (4)$$

The aggregate constant ζ (zeta) is calibrated empirically against a set of age standards and was introduced to circumvent uncertainties in the spontaneous fission decay constant and the neutron dosimetry calibration (Hurford and Green 1983). Suitable age standards are minerals from rocks that have cooled rapidly, such as undisturbed volcanic rocks, and have been precisely dated by other methods, most commonly by Ar/Ar dating.

In the case where the ^{238}U concentration of a mineral grain is determined explicitly using the LA-ICP-MS method (section “[The Laser Ablation ICP-MS Method](#)”), Eq. (3) above is modified to

$$t = \frac{1}{\lambda_D} \ln \left(1 + \lambda_D \xi \frac{\rho_s}{C_U} \right) \quad (5)$$

where

$$\xi = \frac{A}{\lambda_f N_0 R \alpha} \quad (6)$$

and

C_U = concentration of ^{238}U

A = atomic weight of ^{238}U

N_0 = Avogadro’s number

D = density of the mineral

R = average etchable range of one fission fragment

α = detection efficiency for the etched surface

As for the zeta calibration approach described by Eq. (4) above, the aggregate constant ξ (Xi) in Eq. (6) can also be calibrated empirically against a set of age standards. However, all of the constituent constants are known, at least in principle, or can be determined explicitly, so that an absolute determination of the age is also possible.

The External Detector Method

In the external detector method (EDM), spontaneous tracks are measured on an internal surface in the etched mineral grains and induced tracks in an external track detector held firmly in contact with the mineral surface during irradiation. The external detector is almost always a cleaved surface of low-uranium muscovite. During neutron irradiation, some of the induced fission fragments from ^{235}U in the mineral grains leave the surface and enter the external detector. It is important to note that an external detector only receives tracks from one side (2π or hemispherical track registration

geometry), compared to the case of spontaneous tracks etched on an internal surface, which receives tracks from both sides (4π or spherical registration geometry).

After irradiation, the mica external detectors are etched to reveal patches of induced tracks corresponding to each grain in the mineral mount. As the grain mount is not etched again after irradiation, only spontaneous tracks are visible there, while only induced tracks are visible in the external detector. The etched surfaces have a mirror-image relationship to each other and are affixed side by side to a microscope slide for counting of exactly matching areas of spontaneous and induced tracks. Matching between grains and mica is usually automated using a computer-controlled stage.

An age determination by the EDM proceeds by selecting suitable grains in the mount, counting the spontaneous tracks present, and then counting induced tracks over the corresponding area on the external detector. Poorly orientated grains, those with nonuniform uranium distributions, or those with interference from dislocations or other defects, are simply avoided.

An important advantage of the EDM over alternative fission track methods is that data are collected over individual grains. Normally, about 20 grains are counted so that the resultant single-grain age distribution can be tested statistically to see whether they represent a uniform age population or not. Since the 1980s, the EDM has become the standard method for fission track analyses, being applied almost universally of studies of apatite, zircon, and titanite, as well as occasional analysis of other uranium-bearing minerals, such as garnet and epidote.

Neutron Dosimetry

For the external detector, and all other methods of fission track analysis that utilize neutron irradiation, it is vital to monitor the total neutron fluence received by each grain mount during irradiation in order to know how much of the ^{235}U has undergone fission during irradiation. This is accomplished by including neutron flux monitors in the same irradiation package as the prepared mounts. Flux monitors are positioned at the top and bottom of each package to monitor the total neutron fluence received and correct for any flux gradients. Once the neutron fluence is known for each sample in the irradiation package, uranium concentrations can be calculated for each analyzed mineral grain based on the corresponding number of induced tracks recorded in the external detector.

Typically these flux monitors are simply muscovite external detectors attached to pieces of reference glass with a well-known and homogeneous uranium concentration, allowing standard glass track densities to be determined in the etched external detector. Although flux monitors may be calibrated against the absolute thermal neutron fluence (Wagner and Van den haute 1992), the fluence calibration is usually included in the aggregate zeta constant (see section “[The Fission Track Age Equation and Calibration](#)”) so that the standard glass track density is applied directly in the age calculation (Eq. 3).

Neutron dosimetry-based methods have the advantage that they are all based on a ratio of two track density measurements, which have similar properties and are therefore likely to be subject to similar errors that ideally should cancel out. Significant disadvantages include very long sample turn-around times while the samples are away at the reactor and the necessity of handling radioactive materials after they are returned from irradiation.

The Laser Ablation ICP-MS Method

Over the last decade, the emergence of LA-ICP-MS to directly measure the ^{238}U concentration has the potential to rival, and even replace, the EDM (Hasebe et al. 2004). Sample preparation and etching proceeds in much the same way as for the EDM, and, as before, a series of well-oriented mineral grains are selected on an internal surface. Once the spontaneous tracks are counted, the

sample is placed into a laser ablation chamber, and an area of each counted grain is ablated and analyzed in the mass spectrometer.

As grains are typically small (~100 µm), a single laser spot with a diameter of 20–40 µm is usually used to ablate part of the mineral. An inert gas transports the aerosol from the ablation chamber into the plasma torch of an ICP-MS, where the ablated molecules are dissociated and ionized before being bled into a quadrupole mass spectrometer for analysis. The measured ^{238}U signal is then normalized using a stoichiometric isotope of known (or assumed) concentration such as Ca or Si to correct for variations in the ablation volume and the absolute concentration determined relative to a standard of known composition (see “► [Laser Ablation Inductively Coupled Plasma Mass Spectrometer \(LA-ICP-MS\)](#)”).

The LA-ICP-MS method can be applied to a range of different minerals and produces single-grain analytical data of comparable precision to the EDM. This new approach has the additional advantages of simplified sample preparation procedures, rapid and largely automated analysis, and needs only one (spontaneous) instead of three (spontaneous, induced, and standard glass) track densities. Most importantly, however, it does not require neutron irradiation and therefore eliminates the need to handle irradiated materials, resulting in dramatically reduced sample turn-around times. Although significant work still needs to be done on calibration, standardization, and testing, this technique is likely to be adopted much more widely in the near future.

One disadvantage of the LA-ICP-MS method is that it is a destructive technique on a microscopic scale, destroying part of each grain during analysis so that later inspection of the counting results is not possible. However, this shortcoming can easily be overcome if image sets are captured before ablation (see section “[Automation of Fission Track Measurements](#)”), thus creating a permanent digital record of each grain.

Fission Track Annealing and Modelling

It was discovered early in the development of fission track dating that fission tracks are stable over geological time only at relatively low, near-surface temperatures. As the temperature is raised, the radiation damage making up the core of each track is progressively repaired until the track no longer forms a continuous defect that can be revealed by etching. This process of fission track fading upon exposure to elevated temperatures is called *thermal annealing*, or often simply annealing.

Thermal annealing is a kinetic process in which temperature and time can to some extent be interchanged with each other, longer exposure to lower temperatures producing the same effect as shorter exposure to higher temperatures. Each mineral shows a different characteristic temperature range over which fission track annealing occurs, often referred to as the *partial annealing zone*. For apatite this annealing range is approximately 60–120 °C over geological heating times, with significantly higher characteristic annealing temperatures of around 150–200 °C for zircon and 200–250 °C for titanite, although these are not as well constrained as they are for apatite. A quantitative understanding of the track annealing process is critical to the use of fission track analysis for thermochronology.

Environmental parameters other than time and temperature (e.g., pressure, ionizing radiation) have no significant effect on fission track annealing (Fleischer et al. [1965b](#)), at least at the upper crustal pressures under which thermal annealing of fission track occurs in commonly used minerals such as apatite (Schmidt et al. [2014](#)).

Fig. 5 Comparison of the effect of thermal annealing on fission tracks on laboratory (*right*) and geological time scales (*left*). Laboratory annealing data (from Green et al. 1986) show the reduction in mean confined track length (l) relative to the length of unannealed induced tracks in the same apatite (l_0) after heating at various temperatures and times. Similar length reduction is shown by spontaneous tracks in apatites from deep boreholes in the Otway Basin of SE Australia (from Gleadow and Duddy 1981)

Experimental Fission Track Annealing Studies

Thermal annealing of fission tracks in a particular mineral can be studied in the laboratory by observing the effects of different time and temperature treatments on freshly induced ^{235}U tracks on the assumption that these will behave identically to ^{238}U tracks. The degree of annealing is then monitored by measuring the length distribution of confined fission tracks.

The results of numerous such studies have led to quantitative models of fission track annealing in different minerals that may be extrapolated from laboratory to geological time scales (e.g., Laslett et al. 1987; Carlson et al. 1999; Barbarand et al. 2003 for apatite; Tagami et al. 1998 for zircon). Figure 5 shows the effects of laboratory annealing on induced track lengths in Durango apatite over different time scales (Green et al. 1986). The longer the exposure time, the lower the temperature required to produce a given degree of track shortening due to annealing. Extrapolations of the annealing curve for this apatite are also shown for heating times of 10^6 – 10^7 years using the annealing model of Laslett et al. (1987), along with observational data from deep borehole samples from the Otway Basin (Gleadow and Duddy 1981). The Otway apatites show a range of compositional variation, which broadens their annealing behavior compared to the single Durango apatite composition. However, the general consistency and similar form of the annealing curves between the borehole and laboratory results strongly suggests that annealing is being caused by the same mechanism in both cases.

In apatite, another important control of fission track annealing is the mineral composition. Apatites from most geological environments are dominated by fluorapatites, but also grade in composition toward chlorapatite, and, less commonly, hydroxyapatite. Fission tracks in more chlorine-rich apatites are more resistant to thermal annealing than those in fluorapatite as illustrated in Fig. 6. As described earlier (see section “Track Diameter Measurements”), etched track dimensions such as D_{par} also correlate to some degree with composition and may thus be used as a kinetic parameter to assess the annealing sensitivity of a particular apatite.

Fig. 6 The effect of chemical composition on experimental fission track annealing in apatites. The diagram shows the results of an isothermal annealing experiment where four apatites with different chlorine concentrations were annealed at the same temperature, 330 °C, for different times from 1 to 24 h. The higher the chlorine concentration of the apatite, the more resistant are the fission tracks to thermal annealing (Data from PF Green)

Thermal History Modelling

Track shortening during thermal annealing has two important consequences for fission track analysis. One is that each individual spontaneous track in a natural sample experiences a different fraction of the host rock's total thermal history and will shorten to a degree determined by the maximum temperature experienced since track formation. Because all of the tracks are of different ages, being added progressively by radioactive decay, a spectrum of track lengths results that contains a detailed record of the entire annealing history within the temperature range of the partial annealing zone. The second effect is that fewer tracks will intersect a given surface as the average track length gets shorter during annealing, so that the apparent fission track age is reduced proportionately during annealing. Thus, partial thermal annealing will have the effect both of reducing the fission track age and changing the track length distribution. Utilizing fission track analysis for thermochronology involves modelling the information in both the apparent ages and track lengths to reconstruct the thermal history, based on a quantitative understanding of the annealing kinetics from laboratory experiments (see section "[Experimental Fission Track Annealing Studies](#)").

Based on these annealing models, it is possible to *forward* model the distribution of fission track lengths and ages, whereby the two parameters are predicted for any given temperature-time path, and manually compared to the measured data. While this approach is useful to guide further interpretation, it is also relatively inefficient. In *inverse* modelling, a realistic thermal history is reconstructed from a given set of observed fission track measurements of age and length. Such inverse modelling is achieved by conducting numerous, random thermal history trials and testing the simulated forward models for their closeness of fit to the observed fission track parameters. Eventually after a very large number of trials, a number of good-fitting thermal histories emerge that match the observational data within defined statistical limits. However, it is important to note that such model solutions may not be unique, as different thermal histories can result in similar age and track length distributions.

Thermal histories can be further constrained by adding independent geological information (e.g., geochronological data, depositional age, etc.) or by modelling fission track data in conjunction with other thermochronometers such as (U/Th)–He or vitrinite reflectance. Efforts are also being undertaken to allow more sophisticated modelling of samples within their geological context, for example, by modelling a series of neighboring samples simultaneously or by integrating thermal history

modelling with structural or geological models. The strategies for inverse modelling of fission track data for reconstructing thermal histories are discussed in detail by Gallagher (1995, 2012) and Ketcham (2005).

Summary and Conclusions

Fission track dating has been applied to a wide diversity of geological and occasionally archaeological problems, with an early emphasis on dating such exotic materials as meteorite impact glasses and volcanic glasses associated with important hominin fossil sites. These early studies have largely been replaced by a much larger body of work on accessory minerals, such as apatite and zircon, from common crystalline rocks. In this later phase, fission track analysis has developed as one of the core methodologies of thermochronology, and applications to stratigraphic dating have largely given way to other techniques.

The progressive development of a quantitative understanding of fission track annealing under elevated temperatures has led to the major application of fission track dating today in thermochronology, particularly centered on apatite, which is by far the best understood and most commonly used mineral system. Fission track thermochronology has been widely applied to studies of tectonic and exhumation processes in both convergent and extensional settings (see “► [Tectonic Processes \(Thermochronology\)](#)”; “► [Exhumation \(Thermochronology\)](#)”), fault movements (see “► [Fault Zone \(Thermochronology\)](#)”), sedimentary basin analysis, provenance studies (see “► [Provenance \(Thermochronology\)](#)”), and landscape evolution (see “► [Thermochronology, Landform Evolution](#)”). Various applications of fission track dating have been reviewed in Wagner and Van den haute (1992), Gallagher et al. (1998), Gleadow et al. (2002), and Reiners and Ehlers (2005).

Rapid advancements are still taking place in fission track techniques, and in particular, the emergence of new methods involving laser ablation ICP mass spectrometry and automated image analysis are likely to lead to a further transformation of fission track thermochronology in the coming years.

Electron Spin Resonance (ESR) Dating, General Principles

Anne Skinner*

Chemistry Department, Williams College, Williamstown, MA, USA

Synonyms

[Electron paramagnetic resonance \(EPR\)](#)

Definitions

Electron spin resonance: The identification of paramagnetic species through absorption of energy in an external magnetic field.

Electron spin resonance dating: The determination of burial age through measurement of the concentration of free radicals created by natural radiation.

Introduction

To understand electron resonance (ESR) dating, one must, clearly, first understand the principles of electron spin resonance spectroscopy. As the name shows, these principles begin with the nature of atomic structure – a positively charged nucleus surrounded by negatively charged electrons. The technique of ESR spectroscopy was first developed by Zavoisky in 1944. Since then applications have been developed in multiple fields of chemistry and physics, as well as the potential for dating in geology, paleontology, and archaeology. An excellent summary can be found in Rink (1997).

Quantum theory tells us that all systems have a definite energy. Every spectroscopic method involves transitions between two states due to input of energy to a material. If the energy provided to the system exactly matches the difference between two states (resonance), the system can be moved from one state to a higher one, and this yields an absorption signal. Transitions from higher to lower levels also occur, and the emitted energy again provides a measure of the difference in energy between levels. Common techniques in chemistry and physics, defined by the relevant range of the electromagnetic spectrum, are optical spectroscopy, infrared (IR) spectroscopy, and ultraviolet (UV) spectroscopy. ESR spectroscopy almost always involves absorption of energy in the microwave region.

For atoms and molecules, these states can be defined by a series of quantum numbers that are related to angular momentum. ESR spectroscopy, as the name suggests, is concerned with transitions of electrons between states of differing electron spin. As a spinning electric charge, electrons possess a magnetic moment. The interaction of this moment with an applied external magnetic field leads to Zeeman splitting of possible states as shown in Eq. (1), where β is the electron Bohr magneton, H is the applied field, g is the splitting factor for a given system, and M_s is the electron spin quantum number:

*Email: anne.r.skinner@williams.edu

$$\Delta E = g\beta H M_s \quad (1)$$

For a “free” electron, the simplest case, $g = 2.00232$, and we consider only the two possible spin states $M = \pm 1/2$. The associated magnetic moments are equal and opposite in direction. Figure 1 shows the effect of applied magnetic field on the separation between the possible states. The lower state represents a system in which the magnetic moment of the electron is aligned parallel to the external field, while in the upper state they are opposed. Quantum mechanical calculations can determine the energy of a given state. Fortunately, quantitative knowledge of absolute energies is not needed in order to use this technique for dating.

Now we need to remember another chemical principle. Electrons are normally paired, either in atomic orbitals or in chemical bonds. By the Pauli principle, the spins of the paired electrons must be opposite in direction. If, then, such a material is put in a magnetic field, each state will be populated by one electron. If we put in energy to raise the lower electron to the upper state, we have reversed its spin and we now have a forbidden situation, a level with two electrons of the same spin. Thus electron spin resonance can only be observed in systems with unpaired electrons. Such systems are called “paramagnetic,” and an alternate name for the method is electron paramagnetic resonance (EPR). Which term is used is a matter of preference; physicists are more likely to use EPR. The principles are the same; the only problem that this introduces is the need to search under two names to obtain all the available references in the field.

Those readers with experience in optical, IR, or UV spectroscopy will be accustomed to scanning by changing wavelength. The atomic or molecular orbitals have fixed energies. ESR spectrometers scan by changing the magnetic field. Figure 1 shows that the splitting between levels is a function of magnetic field. So we change H until the splitting matches a constant energy, $h\nu$. In theory we could hold H constant instead, but experiment has shown that we get better precision the other way.

There is a second difference between other methods and ESR spectra. In other methods, the resonance signal is indicated by an absorption (or transmission) peak such as that in Fig. 2. Largely because of details of signal acquisition by the spectrometer, ESR spectra are collected as the first derivative of the peak. This has one significant advantage for chemists and physicists. Frequently their interest is in the dependence of the g -value on electronic environment. Using the derivative spectrum, one can more easily see small changes in g -values by measuring the change in position of the point where the signal crosses the baseline rather than by attempting to find the maximum of the peak itself.

Figure 2, of course, shows only the simplest spectrum, isotropic absorption by a free electron. Few ESR spectra match this simplicity. Multiple unpaired electrons, such as those on manganese, result in a spectrum of multiple lines with equal intensities (fine structure). In many cases, g -values are

Fig. 1 Effect of Zeeman splitting on electron energy. As the magnetic field strength (H) increases, the energy difference between the spin states increases. The unpaired electron (*blue arrow*) will move from the lower level to the upper if an amount of energy, $h\nu$, is added to the system

Fig. 2 Relationship of absorbance to first derivative spectrum as seen in ESR spectroscopy

Q	35	1,250

Fig. 3 Spectrum of natural flint with complex peaks

affected by interactions with nuclear spins (hyperfine splitting), and for solid materials, such as those normally used for ESR dating, by variable orientations of crystals with the magnetic field (Ikeya 1993). These, with symbols such as $g_{\perp}$ and $g_{\parallel}$, will be mentioned under specific applications.

Fortunately most of the dating applications can ignore this complication. For a given substance, dating specialists have established the optimum line to measure, whether it be the complex spectrum of aluminum or the anisotropic carbonate spectrum. More problematic is the mixture of elements found in most natural materials. This can yield a complex spectrum of overlapping lines from which the desired information must be extracted by suitable adjustment of experimental parameters,

including temperature of measurement. Figure 3, a spectrum of raw flint, is an example where the spectrum contains contributions from the E' silica peak, a peroxy peak, and organics (plus some others).

Complex spectra can sometimes be resolved by increasing the resolution, separating overlapping signals. The more intense the magnetic field, the easier one can resolve two signals whose g-values are virtually identical. ESR spectrometers are defined by the frequency of the microwave source (see Table 1). The most commonly used type is X-band, but higher bands, especially K and Q, also have a role in ESR dating. There is, however, a trade-off. The higher the band, the smaller the amount of sample used, so that while the precision of the spectrum, in terms of separating signals with very similar g-values, is improved, the quantitation of the signal diminishes. The most useful dating application of Q-band spectroscopy is determining whether signals are related to the same radical species, and therefore, the less-well separated peaks in the X-band can be treated as a single signal (Skinner et al. 2001b).

ESR-Active Materials

So where do we find paramagnetic systems? There are three major classes. “Point defects” are electrons trapped during the formation of certain crystals. They are often responsible for colors. Some atoms, mostly transition metals, have an uneven number of electrons and therefore show paramagnetism. Iron is, of course, a well-known example here. Finally there are molecules which can develop paramagnetism in two ways. First, the molecular structure can be paramagnetic, usually because it incorporates one or more paramagnetic atom. Heme proteins, which contain iron, exhibit an ESR spectrum. Second, a molecule can be made paramagnetic by removing an electron from a molecular orbital. These are called “free radicals.” This class of materials is the one we look to for dating applications.

The free radicals with which we are concerned are created by radiation. There are three forms of nuclear radiation. Alpha (α) radiation is caused by emission of a helium nucleus from the radioactive atom. As this is a large particle, it is easily stopped with an effective range of approximately 20 μm . Beta (β) radiation consists of nuclear electrons. The energy of these particles can vary considerably; in materials common in dating, they are assumed to penetrate about 2 mm. Finally, gamma (γ) radiation is simply energetic photons that, again for this application, penetrate approximately 30 cm. Additionally, radicals can be induced by cosmic radiation, high energy particles with extensive penetration capability (Prescott and Hutton 1988).

Nuclear radiation, whether alpha, beta, or gamma, can break chemical bonds to form radicals; it can also remove an electron from an atom or molecule. One interesting result is the production of the point defects mentioned earlier. Irradiation of colorless gems has been used to simulate rarer colored versions, often without mentioning the artificial transformation (e.g., Steinhäuser et al. 2013). Common radicals in current scientific discussion are those in the atmosphere that result in the “ozone hole.” Low-level natural radioactivity in the environment is continually “damaging” materials. Living systems have mechanisms to repair this damage at these low levels, but once the system has died, radicals begin to accumulate. Not all radicals can be used for dating, however.

Before delving deeper into ESR, one might note that there are other dating methods based on the creation of trapped charge by radiation. Usually electrons are trapped at radiation defects in this process. Collectively they are called “trapped charge” methods. The oldest of these is thermoluminescence (TL), where the accumulated damage is detected by heating the sample and measuring the energy released as the electrons are released from trapped charge sites and migrate to luminescence

centers. Optically stimulated luminescence (OSL) uses photon excitation to release the energy (Aitken et al. 1993).

Geological, Paleontological, and Archaeological Dating

General Considerations

A good dating method requires three things. Firstly the dating signal must be zero, or must be determinable, at the time of the event being dated. Secondly, the signal must change in a predictable and consistent manner with time. Thirdly, the signal must be stable over the time period in question. Paramagnetic systems can be annealed (revert to diamagnetic, or paired electrons) in several ways. A paramagnetic molecule may react with another, taking an electron from the second one. The second one may then become paramagnetic but the first has lost this property. Paramagnetic systems tend to be unstable and anneal spontaneously with time (more on this later). This process can be accelerated by heat.

As examples of the first factor, consider flint artifacts. For most of human history, these were made by flaking natural cobbles. While flint has an ESR signal, the signal we would see would be that accumulated since the flint was formed, not since the artifact was created. Hence we only date flint that was heated in the process of manufacturing an artifact. On the other hand, biological materials such as shell, coral, and teeth do not have a “native” signal that prevents dating. This has been investigated by studying modern examples.

The change in signal intensity with time depends on two factors. The first is the sensitivity of the material to radiation and is relatively easy to discover. Initially a linear dependence on dose was assumed, but that was soon shown to be incorrect (Skinner 1983). For most of the last 30 years, the growth curve shape has been assumed to be a saturating exponential. While this is still largely the case, other dependencies have also been determined. For the aluminum center, for example, it appears that there are two components, and a linear term has been added to the exponential. In other cases, two exponential terms have been suggested (Haskell et al. 1997; Duval 2012). Improvements in instrumental precision are likely to continue to improve our understanding of dose dependence.

The other factor is the dose rate, the amount of radiation delivered per unit time. Dose rates are found by summing α , β , γ , and cosmic contributions. Unfortunately, the dose rate may change with time. Unlike radiocarbon ages, ESR ages depend on the environment of the sample, and that may vary during burial. A cave deposit is perhaps the most stable, but even then the moisture content within the cave may not be constant. A sample taken from a riverbank may not be in its original deposit, so the modern environment we measure to establish an age may not reflect the actual burial history. At present, environmental variability is the greatest source of uncertainty in ESR dating, made worse by an inability to quantify it with a level of precision comparable to that we can achieve in the laboratory when we are measuring ESR spectra. This will be covered in more detail later in this section.

In comparison, determining signal stability is relatively straightforward. Recall that unstable systems, such as our paramagnetic radicals, can be annealed with heat. The degree of heat required, measured both as time of heating and temperature, depends on the stability. For background, consider the kinetics of a reaction. For every reaction there exists a rate law defining the change in concentration of reactant (or product) with time. For the annealing of radicals, that law is very simple. In integrated form,

$$C - C_0 = -kt \quad (2a)$$

where C is the concentration of radicals at time t , C_0 is the radical concentration at $t = 0$, and k is the rate constant which depends on temperature. Conventionally, one measures the signal intensity (proportional to concentration of radicals) as a function of heating time for a fixed temperature. From that one can calculate the half-life (mean lifetime) at that temperature, the time needed to reduce the signal to half its original value, and from that the rate constant, k :

$$0.5C_0 - C_0 = -kt_{1/2}, \quad \text{or} \quad k = 0.5C_0/t_{1/2} \quad (2b)$$

In 1889, the Swedish chemist Svante Arrhenius derived a relationship between temperature and reactivity. Arrhenius' law can conveniently be written as

$$\ln k = \ln A - (E/RT) \quad (3)$$

where E is the energy needed to restore the system to stability, A and R are constants, k is the rate constant, and T is temperature in degrees Kelvin. To use this equation, one measures k at a series of temperatures well above the environment, usually around 100–300 °C, in order to speed the reaction. One then plots $\ln k$ against $(1/T)$. Extrapolating this plot to ambient temperature provides the mean lifetime at this temperature. The extrapolation is usually quite imprecise, but it provides at least the order of magnitude of the mean lifetime in the external environment. The results also depend on the assumption that A remains constant over the temperature range between measured and ambient, but this holds well for this system. Other complications include changes in the ESR spectrum with temperature. Shells and teeth, for example, char at elevated temperatures and the resulting carbon radical can obscure the dating signal (Skinner et al. 2000).

ESR Spectra

With these general principles in mind, let us turn to the details involved in determining the age of a material that has a suitable signal and reasonable signal stability. For ESR dating the mean life of the signal should be an order of magnitude greater than the age being determined (Grün 2007). In theory, what we wish to know is the number of radicals produced as a function of radiation. For this we would normally look to the area underneath the absorption signal. As noted, ESR spectrometers produce the derivative of the signal. It is possible to integrate the signal, but instead we use the properties of the original curve. There is a mathematical relationship between the area under the peak and the full width at half maximum (FWHM). And as can be seen from Fig. 2, FWHM corresponds to the height of the derivative. Thus we can plot the peak height from the signal against radiation dose and obtain a proxy for area. This is only really true for well-shaped lines that are not influenced by other ones. As will be seen in later sections, this is almost never true, but again we can find approximations that are sufficiently close to the actual values that our results are reliable.

As noted earlier, crystalline symmetry affects the g -value. If the radical rotates freely within the crystal, the asymmetry averages out. If not, one can define a series of lines as, for example, $g_{\perp}$ or $g_{\parallel}$. The first and still best-known ESR dating signal is that of a carbonate-derived radical, and as commented briefly earlier, this has an anisotropic component. Experiments with ^{13}C -doped calcite [Callens et al. 1989] suggest that a signal at $g = 1.9973$ arises from hindered rotation of an orthorhombic CO_2 radical. The larger signal at $g = 2.0007$ has a contribution from the hindered rotating species, but also arises from a freely rotating radical. Both signals grow with radiation, so in principle either can be used.

Experimental parameters can be used to accentuate one signal over another in a complex spectrum. The intensity of a signal would be expected to grow with microwave power, and it does so up to a point. For every signal with which we will be concerned, there is a saturation power, above which the signal not only does not grow, but may actually decrease. The explanation for this is reasonably straightforward. In any spectroscopic system, not just ESR, there is a distribution of populations among energy states. For ESR, we need fewer electrons in the higher energy state than in the lower, since otherwise the electron in the lower state, even if excited by the resonant energy, has no place to go. Transitions are constantly occurring between states. The transition from the higher energy spin state to the lower is called the “relaxation time.” As long as the relaxation time is short, electrons will return to the lower state by thermal transfer to the crystal lattice fast enough to leave room for new electrons to be promoted to the higher state by microwave energy. For any new system, the signal intensity must be measured as a function of microwave power. While measurements of a specific line must be taken at powers below saturation, sometimes it is convenient to use saturation to simplify the spectrum. For example, by using powers >5 mW, the E' signal in silica can be suppressed (and conversely, if that line is to be measured, the power must generally be <0.1 mW) (Ikeya 1993).

Another experimental parameter is the modulation amplitude (also called modulation field width). To sharpen the output of the detector, the output current is modulated by a pair of coils mounted on the cavity (see Section C for details). Roughly speaking, this modulation amounts to sampling the output at a given interval, large if a large modulation amplitude, small if not. The larger the modulation amplitude (i.e., the larger the output sampled), the larger the resulting signal. If, however, the signal is complex, then a large modulation amplitude may distort the peak shape, mixing two signals. Some experimenters have deliberately overmodulated the signal, assuming that the mixed signals arise from the same radical and have the same half-lives (Molodkov 1998). Generally this is not true, and this technique is regarded with suspicion by most dating specialists.

How then does one set the spectroscopic parameters? Here we need to rely on experiment. If, using a given set of parameters, the peak heights obtained yield ages that are consistent within experimental error with other methods over a wide time range, then those parameters are the ones to use. This is the test that matters. Whatever “error” is introduced by assuming a Gaussian or Lorentzian line shape for a signal that is clearly neither must be much lower than the error introduced by other factors such as the dose rate discussed in the following section.

Dating Procedure

So to begin a dating experiment, select your sample. Generally the sample is powdered in order to ensure that the signal is independent of orientation within the cavity, and the powder is divided into multiple aliquots. If avoiding this sample destruction is essential, a solid piece can be used, but then one should take measurements at a variety of orientations. Either way, the first measurement is, of course, the spectrum of the native material. Then one takes either aliquots of the powder or the single solid piece and applies known artificial radiation doses. Now plotting the peak height against dose creates a “growth curve.”

The example in Fig. 4 assumes a simple saturating exponential growth. As noted earlier, various groups have found that other ways are appropriate to express the dependence of signal on dose in different materials, including double exponentials (Haskell, et al. 1997) and exponentials with a linear component (Duval 2012).

Extrapolating the growth curve (whatever the function used) to the x-axis gives the accumulated dose, the amount of radiation that the material experienced since formation, or burial. This quantity is variously known as AD (for accumulated dose, or occasionally archaeological dose) or ED

Fig. 4 Example of a growth curve in the form of a saturating exponential

(equivalent dose or environmental dose) or D_e (as before). Careful measurement and using a statistically significant number of points usually means that the error on AD is small.

Converting this information to a sample age can be complex. In the broad sense, the AD is the sum of dose rates times the time that has passed. Mathematically this can be expressed as

$$D_e = \int_a^r D(t) dt \quad (4)$$

As a practical matter, this requires knowing the sample environment. Recall that the contributors to environmental dose include α -, β -, and γ -radiation from radioisotopes inside the sample and in the sediment surrounding it, plus cosmic radiation. As a first approximation, we can express this as

$$AD = AD_{\text{ext}} + AD_{\text{int}} = D_{\text{ext}}t + D_{\text{int}}t \quad (5)$$

Consider first D_{ext} , the external dose rate. γ -radiation can penetrate 30 cm, so essentially one needs to know the complete environment in a sphere of 30 cm radius around the sample. In most cases one cannot determine this absolutely precisely. For one thing, the “top” half of the sphere has probably been removed in the course of excavation. More detrimental, the sediment at most sites is inhomogeneous, the so-called lumpy site.

Several methods have been used to obtain dose rate information. None of them are free of flaws. In situ gamma spectroscopy at the position of the sample can provide both the immediate gamma dose, including the cosmic component, and concentrations of the major radioisotopes from which β doses can be calculated. One difficulty is that this provides only an estimate on the remnant sediment, which may or may not be identical to that removed. Further, calibration of these spectrometers has been a problem (Lyons 1989; for a more recent view see Duval and Arnold 2013).

In a second method, dosimeters are inserted into the site, which measure the cumulative external dose, again the γ plus cosmic contributions. These are based on one of the other trapped charge methods, either TL or OSL. Both types have their proponents and detractors (McKeever and Moscovitch 2003; Richter et al. 2010). Either type of dosimeter must be left in place. Depending on the site, they could be retrieved after as short a time as a week or must remain for 6 months to a year. Thus placing a dosimeter at the precise sample location, needed for accuracy, in most sites

would imply suspending excavation in that area, hardly desirable. As a result, usually these are put in the walls, or other areas where they do not interfere with continued excavation. They therefore may not measure the local dose rate.

Another alternative samples a number of sedimentary units in the site and does a volumetric average of the dose rate from each. This may be needed for sites where a gamma spectrometer is not available, or the cost or complexity of retrieving dosimeters is a problem. However, both collection of a statistically significant number of samples and calculation of the resulting average are complex procedures. In principle, in calculating the volumetric average, one should consider, for example, exactly where every rock or bone is in relation to the sample.

If sedimentary analysis is chosen, there are again different ways of obtaining the analytical information. Gamma spectroscopy can be used for direct measurement of sedimentary radioisotope content in the lab. Another method commonly used is neutron activation analysis (NAA) of sediments. In NAA, samples taken from the site are bombarded with neutrons to stimulate nuclear reactions. Those associated with such elements as uranium, potassium, and thorium, the three most common contributors to environmental dose, give off energy of specific wavelength, with intensity proportional to concentration. The weaknesses in laboratory measurements are first that there may be other isotopes that are not captured, second that the actual intensity of radiation can be attenuated by water and thus the sediment moisture content has to be measured, and third that converting the concentration of, say, uranium to a dose requires assumptions about the chain of daughter products (Murray et al. 1992; Grün 1992). In particular, one has to make an assumption about whether radon has been captured in the sediment and therefore contributed to the dose or whether, as a gas, it has escaped. In addition, one has to estimate the contribution of cosmic radiation.

The approximations do not invalidate the results. When two methods such as TL dosimetry and sedimentology have been used on the same site, they yield similar ages for archaeological materials (Dibble et al. 2012), despite being based on different assumptions.

In comparison one would think that finding the internal dose rate, D_{int} , would be straightforward. For some materials it is. Unfortunately, most of the important materials for ESR dating are more or less porous. We can determine, again, the current level of radioisotopes in, say, a tooth, but from experience we know that this level has accumulated over time, perhaps quickly, immediately after burial, or perhaps slowly and continuously. Determining this uptake is a significant complication,

Fig. 5 Different possible uranium uptake models are defined by the parameter “p” (Figure courtesy of Dr. Bonnie Blackwell)

most notably for teeth but also for shells. Historically one modeled three possible types of uptake: early uptake (EU), in which uptake of uranium was essentially instantaneous; linear uptake (LU), in which the rate of uptake is constant over time; and recent uptake (RU), in which virtually all the uranium is absorbed by the sample in a short period before the sample is recovered. Figure 5 represents these options, using a parameter, p , to define them. Which option is most plausible depends on the sample environment. A constant environment is, naturally, likely to produce an LU age. A sample that is initially buried in a lake that then dries up may well fit the EU model. RU models can occur in two ways. The environment may change suddenly to one with more available uranium, perhaps due to tectonic activity. Or the sample itself may change. There is evidence that by 1 Ma, tooth enamel may develop microcracks, allowing more rapid absorption of uranium (Skinner et al. 2001b). And, of course, intermediate values of p are always possible (Blackwell et al. 2002). Recently a number of researchers have developed a coupled ESR/U Series method for teeth that can determine the time-averaged value of p and thus eliminate much of the uncertainty in uptake (Grün and McDermott 1994).

Determining the true uncertainty in the ESR age is difficult. Of course we know the uncertainty in measurements of, e.g., ED and the modern concentrations of radioisotopes, but we cannot know with the same certainty the history of the site. No matter what method is used to determine D_{ext} , it does not capture the overall variation in moisture, nor possible changes in overburden with accompanying change in cosmic dose. Even radon escape may vary with time. And we cannot quantify what we do not know. Two approaches can increase confidence in the results. One is the “isochron” method for tooth enamel that relies on multiple subsamples from a single tooth (Blackwell et al. 2001). More generally, we can recalculate the age as we vary factors such as average water content or cosmic dose rate (Deely et al. 2011). A simplified example is shown in Fig. 5 where dose rates from approximately 250–600 $\mu\text{Gy}/\text{year}$ still yield ages within the errors on the factors we can quantify. This exceeds variability found in virtually all sites (Fig. 6).

Fig. 6 Dependence of calculated age on external dose rate. As measured, the external dose rate for this sample was 400 $\mu\text{Gy}/\text{year}$. Error bars show 1 σ ; within 2 σ , ages are consistent for a given model over a range of dose rates from about 250 to 600 $\mu\text{Gy}/\text{year}$

Materials Used in ESR Dating

Carbonate

The most successful examples of ESR dating have involved carbonate-containing compounds. The major sample type, mollusks, deserves its own section and will not be discussed further. It is worth commenting, however, on speleothems, which were the first samples dated (Ikeya 1978). “Speleothem” is a general term for a variety of cave deposits resulting from dissolution and reprecipitation in limestone rocks. The general features of speleothem spectra resemble those of some mollusks. The primary difficulty in using them is contamination by inorganic and organic detritus which can lead to interfering peaks in the spectrum and misleading internal dose rates. An interlaboratory cross-calibration (Hennig et al. 1982) showed considerable inconsistencies, including disagreement as to the appropriate signal. Lyons (1989) undertook a systematic study of possible causes. There continue to be a number of studies (Bahain et al. 2011), but also suggestions that ESR is of limited utility for dating speleothems (Döppes et al. 2008).

A number of early studies of continental uplift used ESR dating of coral (Schellmann and Radtke 2004; Skinner 1985). Large coral reefs can serve as both the sample material and the surrounding “sediment.” Although the signal stability in coral should restrict its use to <500 ka, good agreement between ESR and other methods on coral has been found up to about 650 ka without correction for fading (Radtke et al. 1988). This suggests a large uncertainty in mean lifetimes determined by isothermal annealing. U-uptake may also be an issue here.

Other carbonate-containing materials have been considered for dating. Caliche and travertine have contamination problems. Foraminifera from deep-sea cores have been studied, with some success, but more work is needed (Schellmann et al. 2008).

Phosphates

The most useful substance for ESR dating has been tooth enamel. Hydroxyapatite (HAP), the structural mineral in teeth, is a phosphate. However, the ESR signal arises from carbonate inclusions in the HAP crystal, and hence the parameters for measuring are the same as for carbonates. The stability of the signal in enamel has been shown to exceed 10^{15} y (Schwarcz 1985; Skinner et al. 2000), allowing dating from as young as 30 ka to 3–4 Ma. Both ends of this range have been cross-checked with radiometric methods, ^{14}C for the younger samples (e. g., Rink et al. 1996) and Ar/Ar at Olduvai Gorge for the older (Skinner et al. 2001a).

Bone contains the same hydroxyapatite (HAP) as teeth and presumably the same carbonate impurities. Therefore, it would seem that bones could be used for dating. Two factors mitigate against this. The success of dating enamel is in part due to the signal stability attributable to large HAP crystals. Crystal size in bone is considerably smaller. More importantly, bone is quite porous. Uranium can be absorbed more easily, but also leached from bone during burial. This largely prevents precise determination of an internal dose. Early studies (Mascarenhas et al. 1982; Kai et al. 1988) seemed to show that ages could be measured within an order of magnitude and were more reliable for young bones, presumably because there was less time for absorption/leaching episodes. Currently, however, ESR dates on bone should not be considered dependable (Döppes, et al. 2008).

Silicates

Quartz grains in sediment were initially studied using the E' signal measureable at room temperature (e.g., Xu and Zhou 2009). A recent development has been the measurement in liquid nitrogen (LN₂) of optically bleachable signals in quartz sediment building on pioneering experiments by Toyoda

et al. (2000) and others. There are three of them, one deriving from aluminum centers, one from a Ti-H center, and one from Ti-Li. If ages determined for the three centers agree, then one has confidence in the results. These applications will be covered in more detail in a later section.

Quartz, in microcrystalline form, also exists as flint or chert. The presence of flint in many archaeological sites encouraged the dating community to look to all possible dating methods. Unfortunately, since trapped charge methods record all radiation since formation, ESR dating of unheated flint would at best date the creation of the raw material, not its conversion into a tool. The “skinflint” method hoped to get around this by comparing the damage to the outermost layer with that of the core, on the hypothesis that β -radiation from the sediment, present only after knapping, would penetrate the first 2 mm of the sample and provide a contrast to the overall dose (Schwarcz and Rink 2001). Despite some initial success, the lack of additional studies suggests this method is no longer considered valid. The dose history of heated flint, however, begins with the time of heating. Dating heated flint by thermoluminescence (TL) is well established. Efforts to use ESR have been less successful. The quartz-based E' signal used for dating must be extracted from a complex spectrum derived from other minerals and organic inclusions. Its behavior depends somewhat on the heating temperature (Toyoda et al. 1993). If the heating temperature was over about 650 °C, a phase transition prevents the regrowth of the signal. Perhaps most problematic, there is a base “unbleachable” signal (to use the TL terminology) which varies from sample to sample (Skinner and Rudolph 1997). Thus neither the precision nor the accuracy of dating by ESR can match that of TL.

In a related study, heated quartz grains were dated to establish the age of a Lower Paleolithic site in Brittany (Monnier et al. 1994).

Last, but far from least, is the use of the E' signal to study the movement of earthquake faults. Along with the study of speleothems, this was one of the earliest applications. The principle is that the movement of an earthquake fault anneals radiation damage in quartz grains primarily by heat and pressure. Thus the observed modern dose reflects the age since last faulting event. Results may be affected by incomplete resetting – large grains may retain some of the original signal (Buhay et al. 1988). As well as the E' center, signals attributed to germanium, aluminum, titanium and the “OHC” center have been studied. The Ge signal has a short lifetime (in terms of this type of study), estimated to be 100 ka. As noted for the optical bleaching, the Ti center is less stable than that for Al. While good concordance of ages from different centers has been observed, the ESR ages can exceed the geological estimates, presumably due to incomplete resetting (Ikeya 1993). Other studies have agreed better with geology (Fukuchi et al. 1986).

Sulfate Minerals

Gypsum (calcium sulfate) is found in a number of environments as the result of precipitation or evaporation. Sulfite radicals have well-characterized g-values around $g = 2.004$. This is, unfortunately, the same region as the carbonate spectra, so natural gypsum may show both. A second signal at $g = 2.008$ can also be used for dating (Kasuya et al. 1991). Although the mean lifetime appears to exceed 10^{12} years, applications to date have concentrated on the time period <500 ka. They include additional efforts to study tectonics (Mathew et al. 2004). However, a comparison of ESR and TL ages showed consistent underestimation by ESR relative to TL, tentatively ascribed to uncertainty in the relative efficiencies of α -, β -, and γ -radiation in inducing defects (Nambi 1982).

In an interesting extension of ESR dating to other regions of the earth, barite (barium sulfate) dating has elucidated some aspects of hydrothermal vent formation in the depths of the ocean. Although the calculations are extremely complex, due to the shape of these vents, the proof of concept is encouraging (Sato et al. 2011).

Table 2 Materials commonly used in ESR dating. The first column notes whether the material has a signal that is either zero at $t = 0$ or determinable. The second notes whether this signal grows in a predictable manner so that an accumulated dose can be established. Finally the third column notes whether the signal stability is adequate for practical uses. The reliability of ages has been cross-checked by other methods for these materials as well. The greater the number of emoticons (positive or negative), the more confidence in the opinion

Space Science

Ikeya (1993) championed the concept of using ESR dating to study formations on the outer planets, using the $\text{OH}^\cdot$ radical. While too unstable to be measured at ambient Earth temperatures, he believed that the low temperatures in space would allow one to measure an accumulated dose. He did not think that this technique would be ready for use in less than a century, however.

Non-radiolytic Dating

So far we have discussed only free radicals created by radioactivity. In principle, any increase in free radical concentration with time could be used for dating. Oxidation of natural products also creates radicals. Ikeya and coworkers experimented with some preliminary work on organic degradation due to light and/or oxygen. Among the substances tested were oils on potato chips, and blood. In general, however, the signal lifetimes and saturation behavior severely limit the dating potential. A comprehensive review can be found in Ikeya (1993). There has been essentially no further work in this type of application since then.

Summary

This outline by no means exhausts the efforts that have been made to use ESR for dating. The following table can be used for an overview of the current state of ESR dating. It is, naturally,

oversimplified, but generally indicates what materials have been good sources for dating sites and which have serious flaws (Table 2).

A literature search will soon show that aside from the examples quoted above, many other minerals have been tested for their ESR response to radiation. Dating applications are the result of low dose rates delivered over a long period of time. Another major use of ESR for radiation sensitivity is determining high doses delivered over a short period of time, as in accident dosimetry. Since in this latter case signal stability is not an issue, useable materials abound. The future will undoubtedly demonstrate that some of these may be transferrable to the dating category. Certainly there is plenty of scope for experimentation; no scientific field should ever be considered closed.

Luminescence, Coastal Sediments

Barbara Mauz*

School of Environmental Sciences, University of Liverpool, Liverpool, UK

Definition

Luminescence. Light emitted by an irradiated semiconductor during exposure to light or heat. The light intensity emitted by the semiconductor is a function of the absorbed dose.

Luminescence dating technique. Dosimetric technique which determines the amount of absorbed dose in a dosimeter (semiconductor) such as quartz and feldspar and the rate of dose to which the dosimeter was exposed before the moment of sampling.

Coastal sediments. Deposits in the zone near where land and sea meet.

Introduction

Luminescence dating technique relies on the absorption of radiation dose in siliciclastic minerals such as quartz and feldspar. When the grains of these minerals are exposed to daylight for a sufficient length of time during sediment transport and deposition, the luminescence clock of the dosimeter is reset to zero. Besides sufficient resetting, the accuracy of a luminescence age of a coastal deposit depends upon sediment composition, the nature of wetting and drying, and the degree of postdepositional geochemical alterations. In general, the coastal environment is governed by the sea level. In the past, shelf areas have experienced migrating shorelines and associated deposits are today submerged unless the rate of uplift of land is faster than the rate of sea-level change or the sea level was, at the time, higher than today. During glacial periods, the sea level was low (e.g., ~120 m b.s.l. during MIS 2) and was situated at or below the shelf edge, causing subaerial processes to dominate the modern coastal area. During interglacial periods, the sea level was high, but, with the exception of the last interglacial, rarely as high as it is today. Thus, coastal sediments deposited at times of sea-level lowstand (e.g., MIS 2) are rarely uncovered. Likewise, coastal sediments deposited at times of maximum transgression (e.g., MIS 6/5.5) can be hard to find in localities where high rate of sea-level rise exceeds the sedimentation rate at the shoreline. Given the limited dose that luminescence dosimeters can accumulate and the preservation potential of coastal deposits, luminescence ages of coastal deposits are generally <300 ka, and within this range, we should mainly find ages of times when the sea level was at its maximum height and when it was falling.

Table 1 Conceptual frame of tidal and wave processes and the link to daylight exposure of sediment grains (Mauz et al. 2010)

Process	Tide	Wave	Daylight exposure
Intertidal exposure	N/A	N/A	Unrestricted, with the exception of pools. Bleaching limited to surface few millimeters, depth being dependent upon grain-size distribution (reduced sorting, reduced penetration)
Early flood tide, sediment reworking by waves in advancing surf zone	Negligible waxing	Significant wave action causing sediment resuspension. High-frequency fluctuation in turbidity (higher during breaking, lower during shoaling and post-breaking)	Effectiveness determined by location relative to wave breakpoint – higher efficiency in swash zone, lower in surf zone, lowest in zone of wave shoaling
Flood tide, sediment transport within water column and along bed	Significant tidal currents orientated onshore (generally fastest at mid-tide). Finer sediments carried in suspension and intermittent suspension, coarser fraction transported as traction load	Negligible	Effectiveness reduced with depth through the water column, determined by turbidity (suspended sediment concentration). Bleaching efficiency significantly limited for traction load
Late flood tide/slack water, particle settling linked to grain size and flocculation	Waning-negligible	Some wave action in shallow water (depth < wave base)	Effectiveness determined by water depth (i.e., location/altitude on the tidal flat relative to high water) and residual turbidity. Bleaching likely to be more effective for fines retained in water column, but the sedimentation potential for these grains is limited
Ebb tide, potential for bed sediment resuspension and reworking	Waxing-significant tidal currents orientated offshore. Extent of ebb-current reworking linked to location/altitude on the tidal flat – limited on upper part and improved on lower part where ebb currents have sufficient time to gather speed and entrain bed sediment. Finer sediments carried in suspension and intermittent suspension, coarser fraction transported as traction load	Negligible	Effectiveness reduced with depth through the water column, determined by turbidity (suspended sediment concentration). Bleaching efficiency significantly limited for traction load
Shallow-water wave reworking as ebb tide shoreline leaves the tidal flat	Negligible	Significant wave action causing sediment resuspension. High-frequency fluctuation in turbidity (higher during	Effectiveness determined by location relative to wave breakpoint – higher efficiency in swash zone, lower in surf zone, lowest in zone of wave shoaling

(continued)

Luminescence, Coastal Sediments, Table 1 (continued)

Process	Tide	Wave	Daylight exposure
		breaking, lower during shoaling and post-breaking)	

Bleaching

Parameters controlling the degree of bleaching in coastal environments are length of daylight exposure at a given water depth, water turbulence, flow regime, and suspended sediment concentration (SSC). In 4 m turbid water, sunlight shorter than 500 nm and longer than 700 nm is almost completely attenuated (Berger and Luternauer 1987), and at 0.05 g l⁻¹ suspended sediment concentration (SSC), feldspar grains are virtually unbleached after 20 h exposure to light (Ditlefsen 1992). In an estuarine environment, light levels are reduced by three orders of magnitude in the upper 80 cm of the water column (Richardson 2001) due to the presence of SSC. But given that accurate ages were obtained from tidal environments, it was concluded that reworking of sediments through subsequent tidal cycles is crucial for sufficiently resetting the OSL clock (Madsen et al. 2007; Mauz et al. 2010). Table 1 shows that, when combined, the influences of transport and deposition processes, the interaction of tide- and wave-induced sediment transport, and the efficacy of subaerial exposure during low water dictate a high level of spatial and temporal variability in the degree of bleaching. It is good practice to study the suitability of a coastal environment for luminescence dating by examining the residual dose in modern samples (e.g., Brill et al. 2012). However, residual dose data are typically affected by large uncertainties which might impact on the assessment of samples with low doses.

Postdepositional Alteration

In general, any reorganization of the sediment, albeit small, is undesired in luminescence dating because it affects the mineral grains in terms of spatial distribution (Cunningham et al. 2012) and chemical pristineness in a largely unknown manner. Reorganizational processes that may affect the accuracy of the dating result are weathering, lithification, and bioturbation, where the first two are a consequence of wetting and drying and the latter depends on the biological activity in the coastal zone. Wetting and drying as a result of tidal cyclicity was studied by Roberts and Plater (2005) who compiled a readily applicable water-content model based on particle-size distribution, pore-space saturation, and inundation period. Wetting and drying as a result of climate seasonality was studied by Nathan and Mauz (2008) who addressed precipitation of carbonate in the pore space when the deposit falls dry. Mauz et al. (2009) report a 2–32 % reduction of dose rate for samples with significant carbonate content. Another challenge is represented by mollusc shells (Zander et al. 2007) and evaporitic sediment components (e.g., gypsum). These adsorb dissolved ²³⁴U from coastal water that typically deviates from the open ocean with regard to ²³⁴U/²³⁸U activity (see Ivanovich and Harmon (1992) for details on U-activity in ocean waters and uptake process). In this way, these components change the dose rate during burial and create large equivalent-dose over-dispersion (σ_b ; Galbraith and Roberts 2012). Rather unstudied so far is unsupported uranium in organic-rich tidal sediments (Bailiff and Tooley 2000) and in Fe and Mn oxyhydroxide coatings on the surface of mineral grains. Madsen et al. (2005) assume that it is negligible because the

contribution of uranium to the total dose rate of sand-sized dosimeters is rather small. Jeong et al. (2007) show how chemical processes like illuviation and leaching occurring under tropical climate conditions result in mixing of mineral grains, change of dose rate, and, ultimately, inaccurate ages.

Approaches to Dating

Jacobs (2008) reviews 196 studies on coastal and marine deposits originating from Europe, North Africa, South Africa, Australia, New Zealand, and North America. Few attempts were made for Scandinavia, west coast of Africa, East Africa, Arabia and India, southeast Asia and northeast Asia, South America, and the Arctic and Antarctic coasts (Jacobs 2008) reflecting the dominant application of the dating technique to soft sediment coasts outside arid and (formerly) glaciated environments.

Microtidal Sediments

As shown by Jacobs (2008), the majority of studies used soft sediment samples derived from mid-latitude beaches, deltas, barriers and foredunes, marine terraces, and beach ridges. These sediments are deposited in shallow, relatively clear water, often composed of well-sorted and well-bleached siliciclastic sand. They can be dated with high accuracy and precision (e.g., Thomas et al. 2008) even if the sand is young (e.g., Sawakuchi et al. 2008; Costas et al. 2012; Shen and Mauz 2012).

Indurated (hard) coastal sediments (e.g., beachrock) are usually well-bleached but may present problems with regard to dose rate. Most studies assume constant dose rate over time in an infinite matrix (e.g., Jacobs and Roberts 2009; Thiel et al. 2012). This is a fair approach for “old” samples where the uncertainty associated with the estimation of high doses exceeds the inaccuracy associated with the constant dose-rate assumption. For Holocene beachrock samples, however, Thomas (2009) obtained quartz OSL ages that seem to be underestimated, probably due to an overestimated dose rate.

Tidal Sediments

By outlining the conceptual frame and analyzing samples derived from a well-established stratigraphic framework (North Sea; 53°N), Mauz et al. (2010) find accurate as well as inaccurate quartz OSL ages and conclude that well-bleached samples may be obtained from all tidal sub-environments. For the same area, Fruergaard et al. (2011) present similar results which include few age overestimations derived from tidal channel samples. For quartz fine-silt samples originating from a west Korean mudflat (34°N), Kim et al. (2012) obtained ages in stratigraphic order between ~19 ka and ~1 ka. Also, Mauz et al. (2010) show that quartz fine silt from mudflats yields overestimated ages possibly due to high turbidity of the coastal water alongside little opportunities for tidal reworking. Even more challenging are coastal sediments from arctic coasts because transport distances are short, the coastal water is very turbid, and reworking opportunities are limited to the brief polar summer. Despite these conditions, Alexanderson and Murray (2012) found negligible residual doses in surface samples collected from up to 10 m water depth.

Gravel Beach

Conglomeratic deposits of gravel beaches are a challenge for luminescence dating. Not only are sand-sized mineral grains rare, the sediment matrix and geometry are inhomogeneous and standard assumptions (e.g., infinite matrix, homogeneous distribution of radio sources) do not apply. Mellett et al. (2012) avoided these problems by using the sandy matrix of deposits that contained exclusively limestone gravel of low radioactive element content. Jeong et al. (2007) show that gravel deposited in a tropical environment yields inaccurate OSL ages. Simms et al. (2011) used the underside of cobbles with which the clast rests on the beach surface. This approach assumes that the clast was rotated by wave action the last time before the relative sea level fell and was not moved by any environmental activity afterwards. The results from this study are in agreement with the local relative sea-level curve and hence encouraging.

High-Energy Coastal Deposits

High-energy events on coasts are storm surges and tsunamis, eventually lying down washover fan deposits or sand layers of various thicknesses which are distinctively different to the background sediments. Brill et al. (2012) estimated the residual dose in tsunami sand deposited during the Asian earthquake in 2004 to ~40 years, and Cunningham et al. (2011) found negligible quartz residual doses in storm-surge deposits. Sawakuchi et al. (2012) use OSL sensitivity (i.e., OSL signal intensity per unit dose) as a tracer to reconstruct frequency of storm impact on a coastal barrier on the basis of known sediment pathways on the coast. Analyzing washover fan deposits resulting from hurricane strikes, Davids et al. (2010) obtained consistent ages for feldspar and quartz separates indicating sufficient bleaching during such a high-energy event.

Summary

Most coastal deposits are sufficiently bleached and can be dated with high accuracy and precision owing to wave and tidal reworking and homogeneous sediment texture. Exceptions may be deposits laid down under high energy and in turbid water. Inaccuracies, if any, are mostly induced by dose-rate issues such as heterogeneous radiation field in gravel deposits, unknown initial U-activity, and changing dose rate in weathered or lithified deposits.

1 Molluscs, Foraminifera, and Other Carbonate Fossils

2 Bonnie A. B. Blackwell

3 Department of Chemistry, Williams College, Williamstown, MA, USA

4 Definitions

5 **Mollusc:** any member of the Phylum Mollusca. The Mollusca form a diverse group of ~ 85,000 extant
6 species, including Bivalvia (clams, oysters, mussels, scallops, etc.), Gastropoda (snails, slugs),
7 Cephalopoda (octopus, squid, cuttlefish, nautilus, ammonoids, etc.), Polyplacophora (chitons),
8 Sacophopoda (dentilids), Rostroconchia (all extinct), Monoplacophora, and Aplacophora. In the shell,
9 calcium carbonate, as aragonite, low or high magnesium calcite, reinforces a conchiolin (protein) and
10 chitin matrix.

11 **Barnacle:** any of several species of Arthropoda belonging to the Subphylum Crustacea, Infraclass
12 Cirripedia. Among the 1,220 or so species, most are encrusting filter- or suspension-feeding organisms.
13 Although some live as deep as 600 m, about 75% live at depths < 100 m in marine ecosystems, and 25 %
14 inhabit the intertidal zone. Within the intertidal zone, species inhabit a very restricted range of water
15 depth, allowing them to be used to mark paleosealevels with some accuracy. Infamous for fouling ships,
16 docks, and intertidal rocks, barnacles have plates that allow them to close off the internal shell to prevent
17 desiccation.

18 **Foraminifera** (abbreviation: **foram**): any member of the Phylum Foraminifera, a group of marine
19 amoeboid Protista. The Foraminifera comprise both extinct and extant species that all have thin
20 pseudopoda that form an external net for gathering food. Many species are planktonic, but several benthic
21 species live on the deep ocean floor, and a few species can tolerate brackish water.

22 **Carbonate compensation depth (CCD):** the depth at which all carbonate fossils have dissolved from
23 deep marine sediment. The aragonite compensation depth varies from that for calcite. Currently, the
24 depths vary from about 4,200 to 5,000 m, depending on the temperature, pressure, and the amount of
25 dissolved CO₂. In the past, the depths have varied dramatically, especially during the Quaternary.

26 **Aragonite:** a calcium carbonate (CaCO₃) mineral found in speleothems, travertines, carbonate cements
27 in sedimentary rocks, and live and fossilized shelled organisms, like molluscs and barnacles. Aragonite
28 often occurs as acicular crystals in speleothems, travertine, and carbonate cements, but in fossils, it may
29 take other crystal forms.

30 **Calcite:** a calcium carbonate (CaCO₃) mineral found in some speleothems, travertines, carbonate
31 cements in sedimentary rocks, and live and fossilized shelled organisms, like some molluscs. Calcite can
32 occur as rhombohedral crystals if allowed to grow uninhibited, but in fossils, it may take other crystal
33 forms.

34 **Irradiation ramping:** a technique used for very small samples in which only three to eight aliquots are
35 used to build a growth curve. After reading the spectra following the first set of irradiations, about half of
36 the aliquots are reirradiated to higher doses and the spectra for all the aliquots are reanalyzed, using the
37 aliquots that have not been reirradiated to calibrate the spectra for all the newly irradiated samples.
38 Normally, the 0 dose and at least one other aliquot are not reirradiated. The ramping can be repeated as
39 many times as necessary to build the growth curve. Normally, at least 10 different added doses are needed
40 to build a precise growth curve, but as many as 15–20 doses are commonly used in ramping.

41 **Ramped box model:** a model for deriving time-averaged cosmic and sedimentary doses for electron
42 spin resonance (ESR) dating first suggested by Deely et al. (2011). The model uses a series of time-limited

boxes whose end points have fixed dose rates derived from geological, paleontological, or biological criteria that define the sediment cover thickness and water depth. Within the intervening time period, the dose rates are assumed to change at a constant rate.

Introduction

In marine and lacustrine sedimentary units, open-air spring deposits, karst fissure fills, and caves and dating molluscs, foraminifera, barnacles, or other carbonate fossils found in the sediment (Table 1) can provide diverse information for Quaternary archaeological, paleontological, or geological studies. Electron spin resonance (ESR) dates for molluscs and planktonic foraminifera have provided vital geological and paleontological information. More recently, several researchers have used terrestrial molluscs to develop sealevel curves, monitor tectonic uplift, monitor water availability in the desert, and date archaeological finds. New developments in the field include applications for benthic foraminifera and barnacles.

ESR Dating Issues

Although molluscs and some other carbonate fossils can act as moderately open systems for U uptake, the minor discordance between the measured $^{230}\text{Th}/^{234}\text{U}$ and $^{231}\text{Pa}/^{235}\text{U}$ ratios suggests that most U uptake accompanies sedimentation early in their depositional histories. Moreover, given the amount of U they normally absorb, the difference between the EU (early uptake) and LU (linear uptake) calculated ages for most molluscs and foraminifera is usually insignificant compared to their associated uncertainties.

Most ESR analyses on molluscs, foraminifera, barnacles, and other marine shells use the X band, but K band has been applied to molluscan aragonite for dating (Kinoshita et al. 2002). The techniques have also been expanded to recognize irradiated shell for retrospective accident dosimetry and dosimetric monitoring for the food industry (e.g., Ikeya et al. 1984; Nakajima et al. 1993; Raffi et al. 1996).

Aragonitic shells normally show five ESR peaks (Fig. 1; see also Blackwell 1995, Table 2), but calcitic shells have more complex spectra. For the peaks at $g = 2.0018$, 1.9976 , and 2.0007 , trap density is related to Mg/Ca ratios (Mudelsee et al. 1992), which can change with diagenesis, secondary mineralization, and fossilization, making them unsuitable for dating some species. Generally, either the peaks at $g = 2.0014$ and 2.0007 in calcitic shells or the peak at $g = 2.0007$ in aragonitic shells are the most reliable, but that must be tested for each species individually, because complex peaks do occur and peaks other than that at $g = 2.0007$ may be light sensitive in some species (Bartoll et al. 2000). Secondary mineralization can cause interference that affects the accumulated dose ($\mathcal{A}_\Sigma$) measurement and age calculation. Signal lifetimes vary significantly depending on the peak and species (e.g., see references in Blackwell 1995, Table 2). Some species show inflection points in their growth curves, such as the peak at $g = 2.0018$ in *Anadara*, *Katylesia*, *Dorax*, and *Phalium*, making it difficult to select an appropriate set of added doses for measuring $\mathcal{A}_\Sigma$ (e.g., Brumby and Yoshida 1994; Shih et al. 2002). Schellmann and Radtke (2001) advocated using a plateau technique with 40–60 irradiation steps to maximize accuracy in the growth curves. They successfully applied that technique to dating coastal marine units in Patagonia (Schellmann et al. 2008). Dului (2000) showed that the aragonite cuttlebone in cuttlefish preserved measureable signals.

Petrographic, X-ray diffraction (XRD), or geochemical analyses should accompany any ESR date on carbonate fossils or travertines to avoid remineralized and recrystallized samples. Contamination from Mn peaks often requires overmodulation to discriminate the dating peaks. Due to U uptake, modeling may

^aAbbreviations: cct calcite, CO₃ carbonate, argt aragonite, *theoret* theoretically.

^bIrradiation ramping technique involves reirradiating some aliquots, but can take up to 2 years to complete for 8–10 rampings. The number indicates the maximum number of rampings that could be required for small samples.

^cSizes assume little or no diagenesis is present. For diagenetically altered samples, larger samples are needed.

^dFor isochron analysis, the sample size must be increased by a factor of 5–8.

^eFor species that have not been tested for ESR applicability, another 100–200 g is necessary for stability and other background tests.

^fSmaller species may require special techniques or mixing multiple individuals into one subsample.

^gLarge sample sizes ensure sufficient pristine mineral for analysis after mineral separation and for XRD or petrographic analysis to check for recrystallization.

^hFor samples from new study sites or sample types not yet tested for ESR applicability, another 100–200 g may be necessary.

Fig. 1 ESR spectra in aragonitic mollusc shells. Three signals commonly can be used for dating in aragonitic mollusc shells (adapted from Blackwell 2006): (a) The signal at $g = 2.0058$ before and after irradiation measured at room temperature. (b) The signal at $g = 2.0036$ measured at room temperature (293 K) and at 145 K. (c) The signal at $g = 2.0007$ before and after irradiation measured at room temperature.

be required for uraniferous samples that cannot be analyzed by coupled ESR- $^{230}\text{Th}/^{234}\text{U}$ dating. In some fresh and hypersaline systems, the $(^{234}\text{U}/^{238}\text{U})_0$ ratio may also need to be measured or modeled. For each species and signal, the α efficiency factor, κ_α , must be measured. Long-term signal fading may also need to be considered, depending on the peak selected and its thermal stability (see Blackwell 1995, Table 2).

Molluscs and barnacles found in life position give the most reliable dating results, although that does not guarantee that reworking has not affected the unit. Larger species are preferred so that each subsample represents a single individual (Table 1), but several shells can be combined from smaller species, assuming that none have been reworked. Fragmentary samples still need to be speciated. Since species effects do occur, analyzing two or three different species from each unit can increase the dating precision and accuracy. Good agreement between ESR, TL, OSL, ^{14}C , and AAR (amino acid racemization) ages has occurred in studies with *Hendersonia* and *Allogona* using $g = 2.0007$ (Skinner and Mirecki 1993) and in *Lymnaea ballica* and *Cerastoderma glaucum* using $g = 2.0012$ (Molod'kov 1996). Thermal stabilities in *Monauha caucaicala* significantly exceeded those in many marine molluscs. For untested species, ~ 100 g of pristine shell are needed to perform the necessary signal stability and calibration tests.

Data from Blackwell et al. (2012)

Fig. 2 Mn^{2+} interference peaks in barnacles. In RM37B, from Norridgewock, the Mn^{2+} signal completely obscured the unirradiated (0 krad) signal, making it impossible to measure peak heights at the lower added doses (adapted from Blackwell et al. 2010): (a) The Mn^{2+} interference peaks. In the natural sample, the Mn^{2+} signal exhibited its typically complex spectrum centered at $g = 2.0118$. Normally, Mn^{2+} has seven multiplets, but the seventh is off the spectrum to the right. (b) The dating signal at $g = 2.0053$. At higher radiation doses, such as with 112 krad, as shown here, the dating peak's signal height can be measured, but destructive interference may have reduced the height for the A peak, making the peak height measurement inaccurate.

For barnacles, diagenesis or signal interference may cause some samples to be unsuitable. For example, in barnacles from Norridgewock, ME, Mn interference prevented the peak heights from being read (Fig. 2; Blackwell et al. 2010). Similar interference problems can occur in molluscs or foraminifera. Iron contamination can also produce a very broad Fe^{3+} signal interference that tilts the baseline, thus, potentially adding a systematic error to any peak height measurements (Fig. 3; Blackwell et al. 2010). Both benthic and planktonic foraminifera can suffer diagenesis due to carbonate dissolution, if they sit below the carbonate compensation depth (e.g., Tadia et al. 2002). Since the planktonic foraminifera tests are larger, however, they persist longer in deep sediment and are considerably easier to pick from sediment cores. Nonetheless, both planktonic and benthonic foraminifera are datable (Sato 1981; Blackwell et al. 2013), although both may need irradiation ramping to measure enough doses to build the growth curves for these typically tiny samples. In molluscs, heating to temperatures slightly above 100°C can start to zero the dating signals, but do not affect the Fe or Mn signals, allowing the pure interference signals to be scanned and then removed by signal subtraction from the dating sample, a technique that drops the precision, but raises accuracy for the peak height measurements in contaminated samples. This correction is likely applicable to other contaminated sample types, but it remains to be tested.

Exactly how deep in time molluscs and foraminifera can provide reliable ESR dates remains something of an open question. Traditionally, most experts agreed that the range for molluscs tended to be about from $\sim 5\text{--}10 \text{ } \kappa_{\alpha}$ to as old as $\sim 500 \text{ } \kappa_{\alpha}$ (e.g., see references in Blackwell 1995, 2001, 2006), although Barabas et al. (1988) showed that the signal at $g = 2.0036$ in foraminifera exceeded 1 Ma. Dating samples on the young end is hampered by inability to recognize the dating signal in very young molluscs, while the old end is limited by diagenetic alteration and signal stability. Periodically, however, reports surface hinting that the range could be somewhat longer. For example, Vichaidid et al. (2007) reported ESR ages as old as 13 Ma for marine molluscs in Thailand. The reliability for ages this old must await tests for reproducibility or corroborating ages from another chronometer, particularly since overmodulating some aragonitic signals can produce apparently reliable growth curves without inflection points that hide multiple signals that each grow at different dose absorption rates, producing peaks with different lifetimes (stabilities), that can fade or anneal at different rates under different conditions. Blackwell et al. (2013) did report an age of

Fig. 3 Fe interference in barnacles. Barnacles have a radiation-sensitive peak at $g = 2.0053$. In RM32A from northern BC, shown here, the unirradiated (0 krad) signal grew regularly with irradiation, producing an identical irradiated signal. Interference from the Fe^{3+} peak caused the spectrum to have a consistently “tilted” baseline. Nonetheless, measuring the peak height from the top of the A peak to the base of the B peak did allow an age to be calculated, although the high signal-to-noise ratio in the lowest dose aliquots made measuring the peak heights difficult (after Blackwell et al. 2010).

2.29 ± 0.38 Ma for molluscs found encased from Kharga Basin, Egypt, with which Oldowan tools were associated, which suggested that the ESR age might be reliable.

Fossils can be easily reworked by sedimentary processes, such as erosion/redeposition or bioturbation, from older into younger depositional units (e.g., Blackwell 1994; Blackwell et al. 2012). Therefore, any sampling program should collect at least 8–10 samples from each stratigraphic unit or sequence of units to increase the chance that the samples analyzed provide dates related to the event of interest. Nominally, if 4–5 independent grab analyses from one bag of small or thin-walled molluscs or foraminifera all give the same age within errors, their age can probably be considered to date the unit’s deposition, as in Table 2a, for grab samples of *Melanoides tuberculata*. Tables 2b and 2c demonstrate that the weathering state or diagenetic features provides no clue to the ESR ages calculated (Blackwell et al. 2012). For larger shells, 4–5 independent ESR ages that agree well usually provide a reliable date for a given unit.

Although the required sample weight varies depending on the auxiliary analyses necessary (Table 2), the ESR analysis itself, and the associated NAA or geochemical analyses to measure the internal dose rate, require 1–2 g of pristine carbonate per standard ESR subsample. Secondary mineralization or cementation checks require larger samples, as do samples in which diagenesis may have occurred or samples needing to be separated into discrete mineral phases. Table 1 lists the minimum sample sizes normally needed for various sample types. For very small samples (100–200 mg), the irradiation ramping technique, in which several aliquots are reirradiated several times, can be used to get enough different doses to build a reliable growth curve. Irradiation ramping, however, does lengthen the total dating analysis time by up to 1–2 years, due to the special handling necessary.

Since isochron analysis for all samples, except teeth, is still experimental, either associated sediment samples should be collected for sedimentary geochemical analyses or the sampling locations need to be tested with in situ γ or TL dosimetry to ensure accurate dates. For TL dosimetry, the dosimetry site (i.e., the spot from which the samples were or will be removed) needs to be unaffected by further excavation or deflation for 6–12 months while the dosimeters are in place. Due to the high probability of equipment tampering or theft in lacustrine or coastal marine sites, where security can be impossible to maintain over long periods, either γ dosimetry or sedimentary geochemical analyses are preferred over TL dosimetry.

Water, rock, and sediment attenuate the cosmic dose reaching any sample below. Since many marine shells and some lacustrine molluscs are normally deposited in water, the water depth above the sample presents a potential source of systematic or random error in the analyses. For many samples, at some point, more sediment covers the fossil, while the water could disappear due to tectonic uplift, the lake drying, or

Fig. 4 Modeling the time-averaged cosmic dose rates, $\bar{D}_{\text{cos}}(t)$. To account for sedimentation and denudation, time-averaged cosmic dose rates, $\bar{D}_{\text{cos}}(t)$, must be modeled (adapted from Deely et al. 2011): (a) A ramped box model for the mollusc RM79, San Salvador: Instantaneous $D_{\text{cos}}(t)$ were integrated over time to calculate the time-averaged dose rate, $\bar{D}_{\text{cos}}(t)$. This model assumed that RM79 was deposited or lived in 10 cm of sediment under 5 m of water at 125 ka giving $D_{\text{cos}}(t) = 127 \mu\text{Gy/y}$. By 115 ka, another 50 cm of sediment had reduced $D_{\text{cos}}(t)$ to 98 $\mu\text{Gy/y}$. Then, sealevel was assumed to have dropped 5 m in a geologically instantaneous time, which raised $D_{\text{cos}}(t)$ to 194 $\mu\text{Gy/y}$. As the platform was denuded, thinning the sediment cover to 10 cm today, $D_{\text{cos}}(t)$ rose to 252 $\mu\text{Gy/y}$. (b) The effect of $\bar{D}_{\text{cos}}(t)$ on the coral RC42, San Salvador, assuming that its possible depth during growth ranged from 1 to 10 m, and its maximum sediment cover did not exceed 2 m more than its current cover of 1 m yielded ages that ranged from 121 to 128 ± 8 ka. All these ages correlated well with OIS 5e, the known age for the Cockburn Town Reef.

sealevel changes, making it necessary to model the cosmic dose rate changes with time in order to derive a time-averaged cosmic dose rate. For terrestrial molluscs, the speed at which sediment covers the sample must also be modeled to estimate the time-averaged sedimentary, as well as the cosmic, dose rates. In some areas, later denudation may remove the sediment cover, which again will affect both the sedimentary and cosmic dose rates. Several ways to model such changes exist. Deely et al. (2011) used a ramped box model (e.g., Fig. 4a) in which the end points of the ramped sequences were tied to modern analogue species' preferences for sediment or water depth, and to paleodepths and sediment cover thicknesses as estimated from geological observations. When tested, their modeling produced ESR ages that agreed well with known ages for corals from an MIS 5e reef (Fig. 4b). While more mathematically intricate models could be constructed, they likely provide little improvement in accuracy given the uncertainties in the paleowater or sediment cover depths and the time input required to do the modeling. After all, such models are only as accurate as the certainty about the geological conditions under which the sample was originally deposited, which can be sketchy at best for species in coastal plain, lacustrine, or terrestrial settings. For most situations, using time slices of 1 ky for such modeling exercises provides reasonable accuracy, but water and sediment cover depths need to be refined to within 0.1–0.5 m for molluscs deposited in shallow water and to within 1–2 m for species from deeper water up to 200 m (Deely et al. 2011). For species deposited under > 200 m of water or > 100 m of carbonate sediment, the cosmic dose rate is negligible.

174 Applications to Quaternary Studies

175 After Ikeya (1980) first described ESR signals in molluscs, Ikeya and Ohmura (1981), Radtke
176 et al. (1982), Baffa and Mascarenhas (1985), Katzenberger and Grün (1985), Hütt et al. (1983), and
177 Skinner (1986) were among the first researchers to report ESR ages for marine molluscs. They and their
178 colleagues all later applied these methods to problems such as dating (e.g., Dash et al. 2002; Kinoshita
179 et al. 2002) and then correlating coastal marine units (e.g., Mirecki et al. 1995; Schellmann et al. 2008)
180 measuring coastal uplift in tectonically active areas (e.g., Hantoro et al. 1994; Doğan et al. 2011; Tari
181 et al. 2013) or determining the magnitude of sealevel change in order to build paleosealevel curves in
182 tectonically stable areas (e.g., Molod'kov and Bolikhovskaya 2002; Deely et al. 2011). These methods are
183 now well established, although its application in each new study area requires that the tests for signal
184 stability in new species be completed before the dates can be assumed to be reliable. Such ESR studies are
185 often coupled with other applicable dating methods, although mid Quaternary deposits in many areas may
186 lack suitable samples for most methods other than ESR (e.g., Takada et al. 2003; Tari et al. 2013). For
187 more detailed discussions of molluscan dating applications, see Blackwell (1995, 2001, 2006).

188 Both terrestrial and freshwater molluscs can give reasonable ESR ages, depending on the species.
189 Molod'kov (2001) reported ages of 393 ± 27 ka for Layer 5b, for terrestrial molluscs preserved in the
190 Lower Paleolithic site at Treugol'naya Cave, Russia. These dates agreed well with ESR dates on herbivore
191 teeth from the same sequence (Blackwell et al. 2005). Given the inherent differences in the signals in these
192 two chronometers, this suggests that these terrestrial molluscs do give reliable ESR ages.

193 In late Pleistocene dune sequences on San Salvador Island, Deely et al. (2011) showed that the
194 terrestrial mollusc *Cerion* gave ESR dates that agreed with those obtained from corals in MIS 5 reefs.
195 They also used ESR ages on *Codakia*, a marine mollusc that inhabits a very restricted tidal and sediment
196 depth range, to pinpoint sealevel positions during Marine Isotope Stage 5.

197 After Sato (1981) first used ESR to date planktonic foraminifera, applications in pelagic marine
198 sediment have become routine (e.g., Hoffmann et al. 2003). Using ESR, a provenance study recognized
199 foraminifera in Cypriote-style limestone statuettes (Polikreti et al. 2004). Blackwell et al. (2013) used
200 ESR to date benthic late Quaternary foraminifera from the Cearà Rise, in the central Atlantic. Otamendi
201 et al. (2006) suggested that Fe and Mn^{2+} signals in Cretaceous to Eocene foraminifera could be used for
202 stratigraphy and paleoenvironmental reconstruction.

203 Summary

204 ESR dating for molluscs and foraminifera will likely continue to provide valuable geological and
205 paleontological dates that can help to answer questions regarding plate tectonic events, geohazard
206 potentials, volcanic histories, groundwater hydrology, Quaternary climatic and sealevel fluctuations,
207 Quaternary sedimentation and erosion, as well as dating archaeological sites and helping to estimate
208 species' first and last appearances. The future will likely see even more applications to groups of
209 organisms hitherto untested as well as innovative solutions to identify and correct interference problems
210 seen in some species.

Archaeomagnetic Dating

Cathy Batt*

Archaeological Sciences, University of Bradford, Bradford, UK

Definition

Archaeomagnetic dating is the study of the past geomagnetic field as recorded by archaeological materials and the interpretation of this information to date past events.

Introduction

Archaeomagnetic dating is a method for dating fired materials and sediments from archaeological sites, based on their preserved magnetic remanence. The principles of the method can be summarized as follows:

- The geomagnetic field changes significantly on archaeologically relevant timescales of decades and centuries (Tarling 1983, p. 145).
- Some archaeological materials contain magnetized particles, and certain events cause the geomagnetic field at a particular moment in time to be recorded by these particles.
- This recorded magnetization can be measured in the laboratory.
- By comparing the recorded magnetization with a dated record of changes in the geomagnetic field with time, the event which caused the recording can be dated.

The application of archaeomagnetic dating is restricted in time and location to regions where there is detailed knowledge of the geomagnetic field for the period in question. The strengths of archaeomagnetic dating are that it dates fired clay and stone, for example, hearths, kilns, ovens, and furnaces, which are frequently well preserved on archaeological sites; it dates the last use of features, providing a clear link to human activity; it can be cost-effective and is potentially most precise in periods where other dating methods, e.g., radiocarbon dating, are problematic.

The Physical Basis

Archaeomagnetic dating is based on a comparison of the past geomagnetic field, as recorded by archaeological materials, with a dated record of changes in the Earth's field over time in a particular geographical area. The geomagnetic field changes both in direction (declination and inclination) and in strength (intensity) (Lanza and Meloni 2006, p. 34), and archaeomagnetic dating can be based on changes in either direction or intensity or a combination.

*Email: c.m.batt@bradford.ac.uk

Fig. 1 The acquisition of thermoremanent magnetization. Before heating, the magnetic domains within the material are randomly orientated within the ambient field and cancel out. During heating, some domains gain sufficient energy to reorientate in the direction of the ambient field and retain this orientation on cooling, producing an induced magnetization. As time passes, the ambient field changes, but the magnetic domains retain the magnetization at the time of cooling (Adapted from Linford (2006), Fig. 2)

For archaeological material to be suitable for dating, it must contain sufficient magnetized particles, and an event must have caused these particles to record the Earth's magnetic field. Many geologically derived materials, e.g., soils, sediments, and clays, contain suitable iron oxides, such as magnetite, hematite, and maghemite (Merrill et al. 1998, p. 84). There are primarily two types of archaeological events which may result in the Earth's magnetic field at a particular moment being recorded by archaeological material: heating and deposition in water. If fired materials have been heated above the Curie temperature of the iron oxides (typically 650–700 °C), they easily become magnetized in the direction of the ambient field, which is usually the geomagnetic field (Fig. 1). On cooling, they retain this thermoremanent magnetization, which reflects the Earth's magnetic field at the time of last cooling. Suitable archaeological features include hearths, kilns, ovens, and other fired structures. Water-lain sediments may acquire a datable detrital remanent magnetization from the alignment of their magnetic grains by the ambient field

Fig. 2 The acquisition of detrital (or depositional) remanent magnetization. Some sediment particles may be weakly magnetized, usually along their long axes. As they settle through the water column, they are free to rotate and align with the ambient magnetic field. They retain this orientation on settling and become fixed in position by the weight of sediment accumulating above them. They are no longer able to rotate and retain the magnetic direction of the ambient field at the time they became locked in place (Adapted from Linford (2006), Fig. 3)

during deposition (Fig. 2). The magnetized grains then settle and become immobilized, retaining a record of the direction of the geomagnetic field at their deposition. This effect allows deposits in wells, ditches, and streams to be dated. However, uncertainty over the exact moment at which the magnetization is acquired (Evans and Heller 2003, p. 86) and postdepositional disturbance of the magnetization by bioturbation and diagenesis of sediments (Batt 1999) means that almost all archaeomagnetic studies focus on fired materials.

The Method in Practice

Archaeomagnetic dating by direction requires the exact position of the archaeological material to be recorded in relation to the present geomagnetic field, and so the material must be undisturbed and sampled in situ. Careful evaluation of structural remains is required to identify any post-firing movement and to select undisturbed areas for sampling. In addition, the magnetic field in which the feature cooled may be disturbed by the magnetization of faster cooling parts of the feature (Schurr et al. 1984). The presence of magnetic materials, such as iron slag (Abrahamsen et al. 2003), can also cause disturbance. Sometimes such disturbances are not visible on site but will be revealed by statistical analysis of the measurements of remanent magnetization, and so, where possible, different parts of the feature must be sampled and compared (Fig. 3). Samples of robust fired materials can be taken by coring, attaching plastic reference buttons using a fast-setting epoxy

Fig. 3 Archaeomagnetic sampling of a pottery kiln, showing samples taken by the button method from walls, floor, and pedestal

resin, or encasing samples in plaster of Paris before lifting (Linford 2006; Trapanese et al. 2008). Sediments and friable fired materials are sampled by insertion of plastic cylinders. Approximately 15 small (c. 1 cm³) samples are needed from each feature, and it may be possible to select sampling locations to minimize the visual impact. In all cases, the orientation of the in situ samples must be measured, usually by leveling the sample horizontally and marking the north direction using a magnetic or sun compass or a gyrotheodolite. Measurements of archaeointensity have the significant advantage that in situ samples are not required, allowing the dating of bricks from buildings or non-orientated pottery fragments (Shaw et al. 1999). These determinations can be carried out on much smaller samples, depending on the measuring instrument.

In the laboratory, the remanent magnetization of each sample is measured in a magnetometer, and the stability of this magnetization is evaluated by alternating magnetic field or thermal demagnetization (Merrill et al. 1998, p. 90). Demagnetization is necessary as the thermo- or detrital remanent magnetization acquired in the past may be overprinted by a viscous remanent magnetization, caused by magnetically soft materials changing with the geomagnetic field. The distribution of the stable magnetic components is assessed using Fisher statistics (Fisher 1953) to calculate a mean magnetic direction, together with its angular spread (α_{95}).

Dating by direction is relatively experimentally straightforward as the magnetic direction recorded by the sample is directly comparable to the past magnetic field direction. However, dating by intensity is more complex as the strength of magnetization of the sample is influenced not only by the strength of the past field but also by the mineralogical composition and firing regime (Merrill et al. 1998, p. 102). Laboratory techniques have been developed to correct for these factors (Gallet et al. 2009; Tauxe and Yamazaki 2007), but the determination of past intensity involves significantly more measurements than direction, and there are many more potential sources of uncertainty (Gallet et al. 2009). These challenges mean that many past studies have focused on magnetic direction; however, the determination of intensity is becoming routine, allowing definition of the entire magnetic vector (Sternberg 2001).

Having obtained the past magnetic field, the date is obtained by comparison with a secular variation record of changes in the Earth's field (Fig. 4). This record is compiled from direct measurements of the field, where available, and, prior to that, from archaeomagnetic measurements of features or sediments dated by other methods. As the field varies spatially, there needs to be sufficient data with 1,000 km (Noel and Batt 1990), and the development of secular variation records has been the subject of significant recent research. Early studies relied on a visual comparison of magnetic measurements with hand-interpolated calibration curves (e.g., Clark

Fig. 4 Calibration of a mean archaeomagnetic direction in the UK using RenDate (Lanos et al. 2005; Zananiri et al. 2007). The upper graph shows dates when the geomagnetic field had the same inclination as the measured direction; the middle graph shows dates when the declinations were the same. The lower graph shows the combined probability density where the geomagnetic field displayed the same declination and inclination as that recorded by the samples. The black area represents the date range with a 95 % confidence interval, in this case either before 950 BC or AD 1000–1160. Additional evidence is required to select from the two possibilities

et al. 1988). Subsequent developments in the data available and statistical approaches have led to better quantification of errors in both the magnetic direction to be dated and the secular variation record (Batt 1997). This has been followed by the use of Bayesian statistical methods to calculate confidence limits and combine the results for magnetic declination, inclination, and intensity (Lanos et al. 1999; Lanos 2004). New modeling techniques allow the consideration of data over larger regions, reducing the need for regionally specific calibration curves (Korte and Holme 2003). For example, Pavón-Carrasco et al. (2009) used a spherical cap harmonic model to produce a secular variation record for Western Europe. Global models can also be produced (e.g., Korte et al. 2009) using worldwide data, but, at present, these do not have the precision needed for archaeological dating.

Applications

Archaeomagnetic studies have been used to investigate a wide variety of archaeological features. Particularly notable case studies include the dating of medieval and Tudor glassmaking furnaces at Bagot's Park, UK (Linford and Welch 2004), brick kilns (Casas et al. 2007), pottery kilns (Reinders et al. 1999), ovens (Schnepp et al. 2003), and canal sediments (Eighmy and Howard 1991). The precision of archaeomagnetic dates is crucial in their use in addressing archaeological questions. A number of factors will influence this precision: recording of the past field, post-firing or post-depositional disturbance, precision of sampling and laboratory measurements, precision of the secular variation record and the method of comparison, and spatial variation of the geomagnetic field. Of these, the most significant is usually the precision of the secular variation curve, and, as this varies with time, the precision of the date obtained will depend on the archaeological period. As the geomagnetic field has occasionally had the same direction at different times, it is also possible to obtain two or more alternative dates for a single archaeological event. In most cases, the archaeological evidence will indicate the most likely. Given the number of contributing factors, it is not possible to define the general precision of archaeomagnetic dates, but there will usually be an error margin of at least ± 50 years (Linford 2006). It is important to note that the secular variation record improves as more measurements become available; hence, features that cannot be dated or give broad age ranges now may be datable in the future.

Considerable research effort has been focused on building up secular variation records, making archaeomagnetic dating a routine dating tool for some archaeological periods and regions. This includes large parts of Europe, most notably Bulgaria (Kovacheva et al. 2009), the UK (Zananiri et al. 2007), France (Gallet et al. 2002), Germany (Schnepp and Lanos 2005), Iberia (Gómez-Paccard et al. 2006), Greece (Tema and Kondopoulou 2011), and Hungary (Marton and Ferencz 2006). There have also been major studies in the American Southwest, where independent dates are provided by dendrochronology (Sternberg and McGuire 1990; Doyel and Eighmy 1994). Work is progressing in other regions, for example, North Africa (Gómez-Paccard et al. 2012), New Zealand (Stark et al. 2010), and Syria (Speranza et al. 2006).

Longer-term changes in the geomagnetic field include magnetic reversals (Merrill et al. 1998, p. 163), and these major changes can be used to date early hominid sites, if they are recorded in associated sediments (e.g., Parés and Pérez-Gonzalez 1995). In addition, archaeomagnetic studies have been used in estimating firing temperatures (Linford and Platzman 2004) and firing duration (Meng and Noel 1989) and in provenancing studies (Rasmussen 2001; Williams-Thorpe et al. 1996). Wider applications are discussed more fully in Sternberg (2001) and Tarling (1983, p. 157).

Conclusions and Future Directions

Archaeomagnetic dating has been shown to provide valuable archaeological information and supplement the suite of chronological tools available for interpreting archaeological sites. In addition, the development of archaeomagnetic dating as a method contributes to the wider understanding of the Earth's magnetic field (Gallet et al. 2009). As noted by Sternberg (2001), archaeomagnetic dating is most effective as a collaborative venture between archaeologists and geophysicists. Independently dated features from an archaeological excavation can provide geomagnetic field information; once the secular variation pattern is established, it can be used to provide archaeomagnetic dates.

Key to improving the accuracy and reliability of archaeomagnetic dates is the availability of magnetic measurements on dated archaeological material. Collaborative sampling ventures such as AARCH (Archaeomagnetic Applications for the Rescue of Cultural Heritage, http://dourbes.meteo.be/aarch.net/frameset_en.html) have increased the data collected, and they are made widely available through international databases, for example, MagIC (Magnetics Information Consortium, <http://earthref.org/MAGIC/>). In many regions, there has been a focus on directional rather than intensity methods. However, experimentally innovative methods for recovering and interpreting archaeointensity (e.g., Gallet et al. 2009; Casas et al 2005) have led to an increased focus on intensity studies, which permit the full magnetic vector to be used in dating studies, thus improving the precision of dates, and allowing the dating of unorientated material.

Amino Acid Racemization, Eolianites

Colin V. Murray-Wallace*

School of Earth and Environmental Sciences, University of Wollongong, Wollongong, NSW, Australia

Definition

Occurring along many of the world's coastlines, eolianites are geographically extensive, wind-blown accumulations of skeletal carbonate sands derived from the physical breakdown of marine invertebrates from adjacent continental shelves. Eolianite successions have been of interest as archives of long-term environmental change and their potential for reconstructing Quaternary relative sea-level histories. Amino acid racemization (AAR) has been applied to the dating of eolianite successions ("whole-rock" dating) and has involved assessments of relative age, stratigraphical correlation, and, in more ideal situations, the derivation of numerical ages for eolianite units. Fossil molluscs from interstratified shelly facies have also been dated using AAR to constrain the timing of eolianite deposition.

Introduction

Eolianites are stacked, sheet-like deposits of skeletal carbonate sand that crop out along many of the world's coastlines (Fig. 1). The bioclastic sediment comprising eolianite is generated in highly productive inner continental shelf environments, and the sediment is entrained landwards by waves, shallow water currents, and eolian processes. Eolianite sediment typically comprises sand-sized (0.063–2 mm) fragments of skeletal carbonate derived from the physical breakdown of marine invertebrates such as molluscs, echinoids, bryozoans, corals, and coralline algae. Foraminifers and sponge spicules are also commonly present. The term eolianite was introduced by Sayles (1931) in his report on the carbonate dune successions of Bermuda. Non-carbonate minerals may include quartz and heavy minerals. Eolianites have also been described using the lithological term *calcarenite* to avoid the genetic definition, as many facies within these successions were deposited by subaqueous processes. Although by definition, calcarenites contain ≥ 50 % calcium carbonate as framework grains and cement, some eolianites have been noted to have as little as 10 % by mass of calcium carbonate (Murray-Wallace et al. 2001). Eolianite successions represent shore-parallel, composite ancient dune forms which flank many of the world's coastlines. They have been described from coastlines in tropical and temperate regions, and particularly well-described successions occur in the Bahamas, Bermuda, Hawaii, western India, Mediterranean, South Africa, and southern Australia (McKee and Ward 1983; Fairbridge 1995; Vacher and Quinn 1997; Brooke 2001; Bateman et al. 2004; Hearty and O'Leary 2008). Australian eolianite successions extend from Shark Bay, Western Australia, to western Victoria and represent the world's largest eolianite province.

The origin of eolianites has been of global controversy in view of conflicting observations of the field relationships of these deposits (Fairbridge 1995). Along some coastlines eolianites have clearly formed at times of interglacial high sea levels analogous to the present Holocene

*Email: cwallace@uow.edu.au

Fig. 1 Eolianite of Robe Range near the town of Robe, in southern South Australia. Robe Range is a composite barrier structure comprising skeletal carbonate sand units of the late Pleistocene warm interstadials MIS 5c and MIS 5a and capped by unconsolidated but vegetated Holocene dune sand. At this site the tabular cross-bedded sands are separated by weakly developed paleosol. The uppermost unit is capped by a pervasive and strongly indurated calcrete. A person stands as scale at the crest of the structure. The cliff is approximately 20 m high

interglacial such as the Coorong Coastal Plain in southern Australia (Sprigg 1952; Murray-Wallace et al. 1998). This has been confirmed by dating using a variety of geochronological methods, the results of which correlate with sea-level highstands of the past 300,000 years for many of the world's coastlines (Vacher and Quinn 1997). On the Coorong Coastal Plain in southern Australia, the eolianite record extends back in time over 1 Ma (Murray-Wallace et al. 2001). Other coastlines, however, indicate eolianite formation at times of lower sea level during glacials *sensu lato* in addition to deposition during interglacials such as parts of the Hawaiian Islands (Stearns 1985) and the Swan Coastal Plain, near Perth in Western Australia (Price et al. 2001). During such intervals, global ice volumes were larger and sea levels were lower than present. In these situations, eolianites formed in response to stronger onshore winds carrying sand-sized skeletal carbonate fragments landwards from the partially, or completely, subaerially exposed continental shelves. The calcium carbonate was formed at times of higher sea level, and the subsequent landward migration of the carbonate sediment occurred by eolian processes following a fall in sea level (forced regression) or wave, shallow water currents, and eolian activity accompanying a relative rise in sea level (transgressive-related sedimentation). The outer surfaces of the dune accumulations were then consolidated by vegetation cover and soil development. Further evidence for the glacial age (*sensu lato*) of some eolianite successions is that the basal units extend below present sea level implying a lower sea level at the time of their formation and scuba diving has identified erosional shoreline notches within dune limestones that also formed at times of lower sea level (Stearns 1985).

Numerous sedimentary structures are preserved within eolianites from which inferences about relative sea level may be derived (McKee and Ward 1983). Eolian trough cross-bedding and other sedimentary structures (e.g., topset, foreset, bottomset, grain avalanche structures, trace fossils such as animal footprints) represent relational sea-level indicators, having clearly formed above tidal datum (Fig. 1). In settings where active eolian dunes have migrated into standing bodies of water such as coastal lagoons, however, it may be possible to infer relative sea level, albeit crudely, based on the presence of distinctive fossils and interfingering relationships with lagoonal muds.

Eolianite “Whole-Rock” Dating

Despite advances in geochronological methods, it remains a difficult task to establish the age of many Quaternary sedimentary successions and landforms. In many field contexts, requisite mineral phases may be absent (e.g., fossil corals for U-series dating), or the relevant assumptions of geochronological methods are not upheld. AAR has been applied in the dating of eolianites, particularly in contexts where quartz sand is not available for luminescence dating or where entire fossils and other mineralogical constituent are absent that would otherwise have been suitable for dating by other methods (Milnes et al. 1987; Kimber et al. 1994; Kindler and Hearty 1997; Hearty et al. 1992; Hearty 1998; Brooke et al. 2003; Murray-Wallace et al. 2001, 2010). AAR has been applied to dating eolianite successions as the method is applicable to a substantial portion of the Quaternary timescale. Technological advances in the detection limits of amino acid residues in fossils (e.g., reverse-phase, high-performance liquid chromatography) have now made it possible to analyze individual microfossil components from eolianites (e.g., foraminifers such as *Elphidium* sp.).

As with all AAR-based chronologies, the age range of the whole-rock method is a function of diagenetic temperature. Lower latitude sites, characterized by higher current mean annual temperatures, will have experienced higher diagenetic temperatures. Accordingly, the age range of the technique is spatially variable and will be less in lower latitudes than for higher-latitude regions with lower diagenetic temperature histories. Based on a regional study of isoleucine epimerization of eolianite in the Bahamas (current mean annual temperature 23–25 °C), Hearty and Kaufman (2000) concluded that the method is applicable to the past 450–500 ka (i.e., back to about MIS 13). Whole-rock analyses from the Coorong Coastal Plain in southern Australia (CMAT 14.7 °C) have yielded a leucine D/L value of 0.843 for eolianite from the East Naracoorte Range, which based on magnetostratigraphy is regarded as older than 780 ka, and therefore indicating that in this region the practical limit of the AAR method is approximately 1 Ma (Murray-Wallace et al. 2001).

Whole-rock dating is based on the notion that sedimentary particles, if sufficiently well preserved, may be directly dated by AAR and reliably indicates the age of the sedimentary deposit. This is potentially the most complicated application of AAR as considerable background information is required for each field site. Similarly, the results from one field area cannot be assumed to directly apply to another, even within a restricted geographical area. For example, the residence time of sedimentary particles (i.e., time lag between skeletal carbonate formation and their final incorporation within a geological deposit) needs to be quantified for each sedimentary environment. This commonly involves the analyses of modern beach sand, sampled from beach surfaces (e.g., upper 2 cm of sand). Quantification of the residence time may be achieved through calibration by an independent dating method such as radiocarbon dating on a subset of framework grains, but the value determined remains unique to that environment and local field setting.

Dating Eolianites: Analytical Methods

Coarse-grained skeletal carbonate sand (bioclasts) from eolianite is most suited to the whole-rock method (Hearty 1998; Murray-Wallace et al. 2001) as the pretreatment strategies are easier with larger bioclasts (e.g., HCl digestion of outer carbonate grain surfaces). Typically, such sedimentary particles are represented by comminuted molluscs, foraminifers, bryozoans, echinoids, and corals.

An important requirement for whole-rock dating is that the sediment has been rapidly buried and not subjected to prolonged intervals of subaerial exposure, thus significantly reducing uncertainties

about racemization rates and diagenetic temperatures. Shallowly buried sediment (< 1 m) will be characterized by disproportionately high D/L values, a function of the exponential effect of higher, summer temperatures on diagenetic racemization. Accordingly, rapid, deep burial largely removes sediment from the influences of weathering, pedogenic processes, erosion, and subaerial exposure, ensuring that the sediment sampled has remained buried since deposition and is more likely to be better preserved. Collection of whole-rock samples from depths greater than 1 m will ensure that the diagenetic temperature history reflects temperature changes associated with long-term climate changes, rather than seasonal temperature variations. The extent of racemization in whole-rock samples will accordingly represent the integrated kinetic effect of racemization in each of the fossil fragments. Commonly, the most reliable approach for sediment sampling is to auger into the face of an outcrop (natural rock face or quarry exposure) ensuring that the location of the sediment sample is at least 1 m below the natural ground surface. It is also critical from the perspective of diagenetic temperature histories to note the relation of the sediment sample to any subaerial exposure surfaces such as calcrete horizons within the sedimentary succession. Settings subjected to regular alternate wetting and drying should be avoided such as outcrops within the intertidal zone as they are likely to have been subjected to prolonged leaching and diffusive loss of amino acids, particularly in terms of amino acids bound within lower molecular weight peptides and free amino acids. Such contexts also commonly show the effects of reprecipitation of calcium carbonate.

Eolianite sample preparation initially involves the physical disaggregation of sediment to remove any carbonate cement adhering to sediment grain surfaces. Removal of cement involves cleaning in distilled water in an ultrasonic bath followed by an H_2O_2 rinse to remove organic compounds and followed by a dilute acid (HCl) etch to remove any additional cement and the outer portion of sediment grains. The mineralogical integrity of the framework grains can be examined in part through microscopy and X-ray diffraction analysis of an aliquot of the whole-rock sample. Commonly, a subset of sediment grains for AAR analysis are selected through sieving sediment (e.g., particle sizes 250–850 μm ; Hearty 1998; 63–500 μm ; Murray-Wallace et al. 2001). Analyses have commonly been undertaken on the total hydrolyzable amino acids of the intercrystalline fraction, and it is advisable to analyze free amino acids from the same sample before undertaking acid hydrolysis, as an additional means of evaluating integrity of results. Given the complexities of whole-rock dating, analyses of the intracrystalline fraction would also be advisable following the analytical protocol set out in Penckman et al. (2008). More recently the analysis of single foraminifers such as the genus *Elphidium* sp. has greatly enhanced the dating of eolianite (Lachlan 2012) using reverse-phase, high-performance liquid chromatography (RP-HPLC) (Kaufman and Manley 1998).

Complexities in Eolianite Dating

The dating of eolianite is most effective in field settings in which cyclic sedimentation has produced the successions, such as successive interglacials. In these contexts, sufficient time has elapsed between the deposition of different sedimentary units, for them to be statistically resolved based on extent of AAR. A related advantage is that in the most general sense, sedimentary successions of different interglacials may have experienced similar changes in diagenetic temperatures over multiple glacial cycles.

AAR whole-rock sample preparation should also involve the physical removal of strongly abraded and etched grains from the sample population of grains before HCl digestion. The reworking of older sedimentary particles into younger sediments potentially complicates the

application of AAR to whole-rock dating, particularly if the proportion of reworked framework grains is not quantified. Older grains will be characterized by higher D/L values provided that the grains have not lost amino acids through in situ leaching (diffusive loss of free amino acids and amino acids bound in lower molecular weight peptides). The magnitude of reworking of older skeletal carbonate grains into modern sediment will reflect the sediment dynamics of individual study sites and will be a function of local carbonate bioproductivity in the formation of modern carbonate grains and the rate of input of older carbonate grains from the erosion and reworking of Holocene or Pleistocene sedimentary units. In southern Australia, modern beach sediments have yielded high D/L values indicating a significant input of relict carbonate grains from locally outcropping Pleistocene eolianite successions (Murray-Wallace et al. 2001, 2010). At Parsons Beach on Fleurieu Peninsula, South Australia, for example, modern beach sand collected from the uppermost 2 cm of a beach face yielded D/L values of 0.253 for glutamic acid and 0.189 for valine (total hydrolyzable amino acids measured by HPLC) compared with 0.614 and 0.545, respectively, from a last interglacial eolianite succession at Knight Beach on Fleurieu Peninsula (Murray-Wallace et al. 2010). Modern marine molluscs (alive at the time of collection or recently dead) consistently yield low D/L values in the range of 0.02–0.03 for valine and glutamic acid, respectively, further highlighting the magnitude of sediment reworking in the Parsons Beach example. At Long Beach, Guichen Bay near Robe in southern Australia, modern beach sediment yielded a D/L value of 0.225 for leucine (total hydrolyzable amino acids by gas chromatography) and 0.679 for free amino acids (Murray-Wallace et al. 2001). A last interglacial eolianite from a coastal barrier termed Woakwine I (132 ± 6 ka) yielded a mean leucine D/L value of 0.451 ± 0.099 .

Aminostratigraphy

AAR has most commonly been applied to the dating of eolianites in the context of *aminostratigraphy* (Miller and Hare 1980). Aminostratigraphy involves the classification of strata into chronostratigraphical units or *aminozones* that correspond with intervals of time, termed geochronological units (Salvador 1994). Litho-, bio-, and morphostratigraphical evidence is generally used to support these chronostratigraphically defined units, as well as calibration by other geochronological methods. The fundamental unit of aminostratigraphy, the *aminozone*, refers to a single time-stratigraphical unit representing a well-defined interval of time (e.g., single stages of the marine oxygen isotope record) and is delineated by the clustering of amino acid enantiomeric values on replicate fossils from a single, mappable lithostratigraphical unit. According to Miller and Hare (1980), this approach involves the least ambiguous application of AAR data, as it largely overcomes the uncertainties associated with racemization kinetic models and diagenetic temperature histories. Traditional practice has seen the application of this tool in restricted geographical settings to overcome regional uncertainties in diagenetic temperature histories.

By far the majority of applications of AAR have involved stratigraphical correlation and assessments of relative age. The earliest attempts at assessing age equivalence of disjunct sedimentary successions tended only to be undertaken within restricted geographical regions, so that the assumption was upheld that different sedimentary deposits of presumed equivalent age had experienced similar diagenetic temperatures.

Selected Case Studies

One of the first examples of AAR “whole-rock” dating was reported on the extent of racemization of aspartic acid, alanine, leucine, and valine (total hydrolyzable amino acids) in carbonate sediment from a 3 m profile at Piednippie Hall in South Australia (Milnes et al. 1987). Their results revealed a monotonic increase in the extent of racemization down profile with the most promising results for the fast racemizing acid, alanine. Since this early reconnaissance study, whole-rock dating of eolianite has represented a valuable application of AAR in studying Quaternary coastal carbonate successions (Hearty 1998; Murray-Wallace et al. 2001). In a comprehensive study of the geology of Eleuthera Island, Bahamas, Hearty (1998) used the degree of isoleucine epimerization in skeletal carbonate sands as a method for discriminating eolianites of contrasting age. Sediments from eolian dune, beach, and wash-over facies revealed a generally high level of concordance for replicate samples, suggesting that the “whole-rock” method may yield reliable geochronological information for Quaternary morphostratigraphical studies. For example, twelve analyses on a minor paleosol developed on beach and eolian sediments yielded a mean D/L value for isoleucine of 0.379 ± 0.027 (Hearty 1998). The coefficient of variation for these data of 7.12 % compares favorably with results typically obtained on fossil molluscs from a single deposit (Murray-Wallace 1995). Thus, although the age of lithoskels comprising skeletal carbonate sands may be potentially of contrasting ages, the overall averaging effect in well-sorted sand may yield a high level of reproducibility in replicate analyses. Using the whole-rock method, Hearty (1998) was able to discriminate interglacial deposits on Eleuthera Island correlating with MIS 1, 5a, 5c, 7, 9/11, and ≥ 13 .

The whole-rock method has also been applied to a succession of eolianite coastal barriers of the Coorong Coastal Plain in southern Australia (Murray-Wallace et al. 2001). Up to thirteen well-defined barriers occur across the 90 km coastal plain associated with deposition during interglacial sea-level highstands since the onset of the middle Pleistocene (Murray-Wallace et al. 2001). The ages of the barriers had previously been determined on the basis of luminescence dating (Huntley et al. 1993, 1994). Samples for whole-rock dating were obtained from the same stratigraphical units studied by Huntley et al. (1993, 1994). The extent of leucine racemization (total hydrolyzable amino acids and free amino acids) in the Pleistocene skeletal carbonate sand (63–500 μm) increases monotonically with age and is consistently higher than for entire fossil molluscs from the same stratigraphical units, reflecting the lengthy residence time for bioclasts within the study area (Murray-Wallace et al. 2001). The extent of racemization in the whole-rock samples conforms to a model of apparent parabolic kinetics, and the numerical ages determined on the basis of degree of leucine racemization were generally in accord with the luminescence ages reported by Huntley et al. (1993, 1994). The oldest amino acid racemization-derived age of 935 ± 178 ka was for eolianite from the East Naracoorte Range, which is known to predate the Brunhes-Matuyama boundary (> 780 ka).

Summary and Conclusions

Amino acid racemization has been applied in establishing geochronological frameworks for eolianite formation for a range of Quaternary coastal successions from around the world. The principal advantages of applying AAR to the dating of eolianites include the ability to derive relative ages significantly beyond the range of radiocarbon methods (> 50 ka) and, for some coastal regions, significantly beyond the range of U/Th or traditional methods of luminescence

dating and accordingly resolve the ages of several interglacials. With refinements in chromatographic detection of amino acids such as reverse-phase, high-performance liquid chromatography, it is now possible to analyze individual carbonate grains or foraminifers and examine the dynamics of sedimentary environments (e.g., quantify the magnitude of reworking of sedimentary particles). The analysis of eolianites by AAR is a far from trivial task and the “black box” approach to analysis should be avoided.

Luminescence, Flints and Stones

Daniel Richter*

Department of Human Evolution, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany
Lehrstuhl Geomorphologie, University of Bayreuth, Bayreuth, Germany

Introduction

Most applications of luminescence dating of flints and stones are related to archaeology and the timing of prehistoric sites. Here, prehistoric human activities are directly dated in most cases, using the last heating of flint, chert, limestone, quartzite, or quartz. This is in contrast to surface exposure dating of such materials, where the event dated – the last exposure or burial – is often not related to the event of the human occupation or activities. Consideration of the relation between the event dated and the research question asked (i.e., sedimentology, human activity, etc.) is crucial. This is well discussed in Dean (1978), who describes a “typology of events.” Luminescence dating is especially useful in archaeological context at the limits or beyond the range of radiocarbon dating of organic material or when the latter is lacking (see “► [Luminescence Dating](#)”). The time span of application ranges from a few to several hundred ka. However, recent developments employing orange-red TL (Richter 2011) suggest applicability close to 1 Ma under favorable circumstances.

Thermoluminescence (see “► [Quartz Defects, Optically Stimulated Luminescence and Thermoluminescence](#)”) is often employed for determining the heat exposure age, but in principle, optically stimulated luminescence (OSL, see “► [Quartz Defects, Optically Stimulated Luminescence and Thermoluminescence Cosmogenic Nuclides](#)”) can be employed as well. However, OSL is not generally applicable to materials classed as flint, obsidian, etc., and therefore, only few studies investigate such theoretical venues (Schmidt and Kreutzer 2013; Poolton et al. 1995; Polymeris et al. 2010). Rock material without significant amorphous phases, i.e., containing significant amounts of α -quartz (see “► [Quartz](#)”) such as unheated quartz pebbles, is also suitable for surface exposure dating (see “► [Luminescence, Rock Surfaces](#)”). Here, the time of the last exposure to light is dated (e.g., Sohbaty et al. 2012; Kouremenos 2008) which is not necessarily a prehistoric human activity, such as turning rocks over (e.g., Greulich and Wagner 2009).

Luminescence of Heated Flint and Stone

The principles of dosimetric dating (see “► [Luminescence Dating](#)”) and associated physical phenomena (see “► [Radiation and Radioactivity](#)”) apply. The radiation dose, as determined by luminescence methods, is caused by ionizing radiation from within the sample as well as its surroundings. The ratio of radiation dose (palaeodose, P) to dose rate ($\dot{D}$) provides the age. Archaeological flint and stones (luminescence properties) as well as their context (dosimetry) exhibit some specific aspects which are different from other applications of such methods, such as ESR or optical dating (Richter 2007).

*Email: drichter@eva.mpg.de

Fig. 1 Three different methods for estimating palaeodoses (P_1 , P_2 , P_3) (a) additive TL signals in blue, where NTL is the natural TL signal and NTL+D is the natural TL plus the TL induced by additional artificial irradiation; (b) solid lines show the theoretical signal growth with dose (d) of the additive (light blue) and regeneration dose growth curves (light red), both exhibiting supralinear behavior. Dotted lines show fitted data (plotted as peak heights) with regression analysis respectively. (c) Regeneration TL signals in red, where RTL+D is the TL from artificial irradiation after having heated the sample. The sum of the regression (dotted blue) of the additive growth curve (dotted blue line providing the equivalent dose, D_e) and the regeneration growth curve (dotted red line providing the supralinearity correction, D_s) are giving the total absorbed dose (palaeodose, P_1) in a multiple-aliquot additive regeneration (MAAR) protocol. Shifting of either growth curve (slide) along the x-axis (dose) provides P as well (P_2), while interpolation of the natural signal on the regenerated dose growth curve determines P in a single-aliquot regeneration (SAR) protocol (P_3)

Samples and Sample Selection

Samples are primarily selected on the basis of suitability for dating. In the case of heated material, macroscopic features like crenation, reddening, craquelation, potlids, etc., are strong, but not conclusive (e.g., Richter 2007) indicators of heat alteration of lithic material. In most contexts, natural fires can be excluded as cause of the heating (Richter 2007; Alpersen-Afil et al. 2007); however, the time difference between anthropogenic and natural firing is likely not significant in most circumstances (Richter and Krbetschek 2014a). The sufficiency of the prehistoric zeroing for dating application can be tested for by using the material's luminescence properties, such as the presence of a heating plateau and an equivalent dose plateau (Aitken 1985). Sample size requirements depend on the technique/protocol used to evaluate the palaeodose (see below). In any case, the outer 2 mm of samples are sawn off in order to exclude those parts which have received a radiation dose from α -/ β -radiation originating from outside the sample. Thus, the number of parameters in age calculation is reduced and precision is increased. However, this requires minimum sample thicknesses of 5–6 mm, and thus several grams of weight, mostly dependent on sample shape. For standard techniques based on multiple aliquots, about 1 g of material has to remain after the removal of the outer 2 mm, but much less is required for single-aliquot procedures (Richter 2011).

For optical dating of surfaces of rocks, the outer 2 mm surface area is not to be removed because of limitations in the bleaching depth of the light causing the zeroing of the signal.

Palaeodose Determination

The thermoluminescence (TL) signal of most heated flint and stone samples exhibit (significant for flint) supralinear growth of the TL signal with dose/age (Fig. 1). This behavior is also seen in inclusion pottery dating (see “► Luminescence, Pottery and Bricks”; Aitken 1985). In the standard application of the technique, several groups of multiple aliquots (subsamples) receive a suite of

irradiations from a calibrated ionizing source (see “► [Radiation and Radioactivity](#)”). While the dose producing the natural signal (palaeodose, P , or equivalent dose, D_E) is not known, increasing the luminescence signal by several artificial irradiation steps of known dose (dose points) provides the sensitivity (slope of luminescence versus dose) of each individual sample to ionizing radiation. Regression analysis of the measured luminescence signals that are given artificial doses (additive dose growth curve in Fig. 1) provides an equivalent dose (D_E) in the multiple-aliquot additive dose (MAAD or MAD) protocol. The supralinear growth of the signal at low doses is considered by a second regression (supralinearity correction, D_I) of luminescence signals from aliquots which were zeroed in the laboratory prior to irradiation (regeneration dose growth curve). In this multiple-aliquot-additive-regeneration (MAAR) protocol, the sum of D_E and D_I provides the total absorbed dose (palaeodose, P) the sample has received since its zeroing in antiquity (Aitken 1985). Extrapolation procedures for large palaeodoses when the natural luminescence signal is at the onset of saturation, however, are prone to error and not precise. In such cases, the palaeodose can be determined by sliding one of the two dose growth curves along the dose axis until they match (Fig. 1) and the absolute value of the slide provides the palaeodose (e.g. Mercier et al. 2004). In single-aliquot regeneration (SAR) techniques, the natural luminescence signal is just interpolated on a regenerated dose growth curve (Fig. 1) (Richter and Krbetschek 2014b). So far this technique appears to be restricted to heated flint using the orange-red thermoluminescence (Richter and Krbetschek 2006; Richter and Temming 2006) and has not been applied regularly. However, it allows the dating of rather small samples (Richter 2011), which is also possible in OSL techniques (see “► [Luminescence Dating](#)”) which are commonly based on a SAR protocol, as well as for dating heated materials or in surface exposure dating.

Dosimetry

The dosimetry (see “► [Luminescence Dating, Dose Rate](#)”) in luminescence dating of flints and stones can be grouped into internal and external dose rates. The former stems from the content in radionuclides of the sample (commonly U, Th, K) and is determined by geochemical analysis (e.g., see “► [Neutron Activation Analysis](#)”). A common value for the sensitivity of the sample to α -radiation (a- or b-value) is often assumed for quartz pebbles (in addition to the assumption of a small internal dose rate) but should be individually determined for at least the majority of samples especially in heated rock TL dating, because of large variability even within supposed single sources of the origin of the material (especially flint). Recent analysis has shown that significant variation is exclusively correlated to macroscopic visible differences in flint (Schmidt et al. 2013), which is the most commonly employed material. These visible differences include veins, inclusions, etc., which have to be removed in any case, because they obviously belong to different mineral phases. The luminescence properties of different phases are likely to be rather different, and such composite signals cannot, a priori, provide accurate results. Therefore, with the removal of such phases, and other geochemically instable parts like patination, the assumption of insignificant variability is valid, and the internal dose rate can be considered as stable over the entire time range of the method.

The external dose rate originates from outside the sample, i.e., radionuclides contained in the surrounding matrix (sediment, éboulis, gravel, blocks of stone, cave walls, lithics, bones, etc.) and a cosmic contribution. Surprisingly in most cases the assumption of constancy of the external dose rate (see “► [Luminescence Dating, Dose Rate](#)”) appears to be valid but should always be verified by laboratory gamma spectrometry to the extent possible. In heated rock dating, the contribution from external α -/ β -radiation does not have to be considered because of the removal of the outer 2 mm. While these could be modeled, the complex shapes of especially artifacts would presumably result in low-accuracy age determinations. The, usually small, cosmic dose rate depends on depth of burial,

altitude, and latitude and is considered as stable. The external γ -dose rate often dominates the total dose rate, and ages are thus very dependent on the accurate determination of this parameter (see Richter 2007; Table 1 for a hypothetical example). Because samples are almost always removed from context prior to dosimetric analysis, the external γ -dose rate cannot be measured at the exact location of the samples. If sediments are heterogeneous (e.g., in caves), analogous locations of geometries similar to the sample positions are required for in situ measurements by portable γ -spectrometry or dosimeters in 30 cm deep holes ($4\text{-}\pi$ geometry). Alternatively, each excavated surface ($2\text{-}\pi$ geometry) can be measured with portable instruments (Guérin and Mercier 2012). A discussion on the implications of the external dosimetry and methods used can be found in Richter (2007); and Richter et al. (2014). Because the external γ -dose rates cannot be determined at the find spot, it is advisable to approach the age of a lithic assemblage by measuring multiple samples and employ an average external dosimetry from several readings (Richter 2007). This often results in large uncertainties associated with this parameter and consequently large uncertainties in individual ages. Such derived average external dose rates do not necessarily correspond to the dose rate the sample actually was exposed to during burial, and the resulting individual TL ages may be too young or too old. This results in large spreads of TL ages for a given context, and the individual sample ages have to be interpreted with caution. However, this can be overcome by dating multiple samples from a context, yielding an average TL age derived from all samples. This provides a good representation of the context age (e.g., Richter and Krbetschek 2014a). Obviously, averaging requires strong indications of the validity of the assumption that the heating of samples took place roughly at the same time. Alternatively, the external γ -dose rate can be modeled, and the dosimetry estimated for single samples (Guibert et al. 1998; Guérin 2012), provided that the heterogeneity of the sediments is extremely well documented. In general the confidence in TL-dating results of heated flint depends on the ratio of internal to external dose rate, where samples with large internal (stable) dose rates are considered more reliable than others (Richter 2007).

Application of Luminescence Dating of Flint or Stone

Luminescence dating of heated flint and stone is playing a major role in establishing chronostratigraphies, e.g., for the expansion of humans out of Africa or the settlement of Europe. TL dating of heated flint established the quasi contemporaneity of early modern humans at Skhul (Mercier et al. 1993) and Qafzeh (Valladas et al. 1988) at >100 ka and with Neanderthals (Valladas et al. 1987) at about 60 ka in the Levant. These studies showed for the first time a potential time period for these species to meet; however, actual evidence of such is still missing. The antiquity of elaborate figurative art of ca. 40 ka was shown by standard TL protocols for heated flint by Richter et al. (2000) for the site of Geißenklösterle cave in Southern Germany. This site yields some of the most intriguing examples of the Upper Paleolithic art, with figurines made from ivory depicting animals as well as humans. TL-dating results agreed only with some of the available radiocarbon data, the latter of which showed a variability considered as inconsistent with site formation. However, it was not until the improvement of pretreatment methods of radiocarbon dating of bone until excellent agreement was shown between ^{14}C and TL (Higham et al. 2012). While these samples had their natural TL well within the linear dose range of heated flint, artifacts from Menez-Dregan I (France) could only be dated by the slide method, due to their antiquity of ca. 200 ka (Mercier et al. 2004). Heated flint artifacts from the Middle Paleolithic lake site of Neumark-Nord 2 rarely exceed weights of 5 g, inhibiting the application of standard MAAR regression procedures. The application of a SAR protocol resulted in an Eemian (early last interglacial) age for the last

heating, which is in excellent agreement with stratigraphy, palynology, sediment OSL, and magnetic dating (Sier et al. 2011; Richter and Krbetschek 2014b).

Less frequently used materials sometimes provide specific challenges, especially for dosimetry. The general assumption of homogeneous distribution of radionuclides is not valid in quartzite, and internal microdosimetric modeling is required to determine reliable ages (Tribolo et al. 2006). An age of 74 ± 5 ka was obtained for five burnt lithics of the Still Bay layers at Blombos Cave (South Africa). This result is in good agreement with both ESR dates on teeth and OSL dates on sediment (Tribolo et al. 2006), demonstrating the antiquity of “modern behavior” in Africa. Heated limestone was dated by Roque et al. (2001) for the Upper Paleolithic site of Combe Saunière (France). The problem of spurious TL, usually interpreted as the result of a decarbonation process, was avoided by measuring the TL from the calcite crystals in a carbon dioxide atmosphere. TL dates obtained were found in good agreement with radiocarbon dates.

The last heating of lithic material can be dated by optically stimulated luminescence (OSL) for some materials as well. OSL dating of heated rock sandstone revealed consistent ages around 8 ka for clusters of hearths in the Saharan Fazzan Basin (Libya), which will allow more detailed reconstruction of the Neolithic use of the landscape of this area (Armitage and King 2013). Quartz does not need to be heated for dating purposes, but the event dated is then the last exposure to light, routinely used to determine deposition ages of sediments (see “► [Quartz Defects, Optically Stimulated Luminescence and Thermoluminescence](#)”). Excellent agreement was obtained for OSL dating of the outer millimeter of the buried surface of a rockfall boulder with the OSL dating of quartz grains from the underlying sediment, as well as with AMS radiocarbon estimates of a cottonwood leaf found immediately between the clast and the underlying sediment (Chapot et al. 2012), implying a minimum age of 900 years for the creation of the rock art. Application of OSL is by no means limited to archaeological context, and satisfying agreement was obtained for unheated Holocene beach cobbles, from which the buried undersides were dated (Kouremenos 2008).

TL dating of heated flint artifacts has also served to detect site disturbances. A previously unnoticed severe mixing of a Paleolithic site was indicated by the large variability in TL-dating results of heated flint from an assemblage believed to represent a short time span. The age differences of two samples from the same layer with ages of 38 and 5 ka can only be explained by sedimentary disturbance (Debenham 1994). TL dating can further provide indications for the correct attribution of mixed lithic assemblages to technocomplexes. In the case of the Paleolithic site of Chez-Pinaud Jonzac, the TL results for burnt flints from a mixed context provided age estimates in accordance with the result of the lithic analysis, suggesting an Upper as well as a Middle Paleolithic occupation based on diagnostic artifacts (Richter et al. 2013).

Conclusions

Luminescence dating of flint and stone is an important tool, especially in establishing chronologies for the Paleolithic period by determining the age of lithic assemblages through dating the last heating of artifacts. Thermoluminescence dating of heated flint has a major impact in our understanding of the later human evolution, especially the spread of early modern humans and the replacement of Neanderthals. The most useful time range lies beyond the calibration range of radiocarbon dating, because the precision achieved with luminescence methods is often not high enough to answer chronological or chronostratigraphic questions related to Late Upper Pleistocene and later period research. In the light of achievable uncertainties, it always has to be considered if these techniques

actually can provide results capable of answering the question raised. Individual uncertainties in ages at 1- σ between 5 % and 10 %, which is 10–20 % at 95 % probability, can be achieved, and precisions of about 3 % (1- σ) can be obtained for weighted average ages when the same context is dated by multiple samples. Such a precision is comparable to calibrated radiocarbon data at the limits of the ^{14}C method. Dating of objects larger than twice the range of β -radiation includes a stable dose-rate component which increases confidence in age result. The various luminescence techniques employed in dating flint and stone have been shown to agree very well with other dating evidence, while often having the advantage that a human action is directly dated.

Uranium-Lead, Metamorphic Rocks

Daniela Rubatto*

Research School of Earth Sciences, The Australian National University, Canberra, ACT, Australia

Definition: The word metamorphism derives from the Greek word “metamorphosis,” meaning change of form. Metamorphism is the process by which the mineralogy of rocks is changed as the result of pressure and temperature according to their composition and with the aid of fluid and deformation. Metamorphism is mainly concerned with the changes that take place when rocks are in the solid state, even though melt can be one of the phases present.

Introduction

Dating of metamorphism in general aims to determining the absolute age of stages or phases of metamorphism. It requires dating of a mineral or mineral growth zone that reacted or formed during metamorphism. The age is determined by measuring the U–Th–Pb isotopic composition in the mineral (see ► [Uranium-Lead Dating](#)). The crucial step in dating metamorphism is to relate an absolute date to a metamorphic stage or reaction, ideally identified by specific pressure and temperature values. This step is particularly challenging for U–Pb dating as the minerals used are minerals that are typically present in minute amounts within a rock (i.e., accessory), and their behavior and stability during metamorphism are not always well known or easily determined.

Methods

In principle all the analytical techniques used for U–Pb geochronology in other settings can be used for dating metamorphic rocks. Minerals in metamorphic rocks naturally exhibit growth zonation as a result of multistage evolution over a range of conditions throughout their history. While zoned minerals are a powerful tool to reconstruct metamorphic evolutions, the accurate dating of metamorphic stages from the analysis of zoned minerals requires micro-sampling. Microbeam techniques such as ion microprobes (see ► [Secondary Ion Mass Spectrometry: SIMS](#)), laser ablation–inductively coupled plasma mass spectrometry (LA-ICPMS), and electron microprobes (see ► [Chemical Isochron Uranium-Lead: CHIME](#)) are thus most widely used to date metamorphic U–Th minerals. These techniques achieve precise age determination (± 1 % for SIMS and LA-ICPMS) by analyzing small crystal domain (20–50 microns across for SIMS and LA-ICPMS and a few microns for CHIME) in situ, i.e., directly on the polished surface of a crystal.

The identification of the specific growth zones in U–Th minerals is achieved through chemical imaging (Fig. 1). Backscattered electron imaging can be used on all the minerals, but the internal zoning in zircon and baddeleyite is best imaged using cathodoluminescence. Both these imaging

Fig. 1 Images of internal zoning of U–Th minerals from metamorphic (metam) rocks. (a) Light microscope photomicrograph of a zircon with diamond inclusions (Kokchetav UHP gneiss). (c, d) Cathodoluminescence images of zircons. (b) Zircon from a migmatite of the Central Alps that shows two distinct metamorphic overgrowths on a bright detrital core. The metamorphic overgrowths are different in age and both formed during migmatization (Rubatto et al. 2009). (c) Zircon from an eclogite-facies schist from New Caledonia that preserves relicts of the magmatic zircon, domains that record low-temperature alteration at the ocean floor, and high pressure rims formed during subduction (Spandler et al. 2004). (d–g) Backscattered electron images. (d) Monazite crystal from a migmatite from Sikkim, Himalaya, with two distinct growth zones formed during metamorphism (Rubatto et al. 2013). (e) Allanite grain from an amphibolite facies rock the Central Alps, Switzerland (courtesy of Katherine Boston, ANU). The spectacular zoning corresponds to different allanite compositions. Both the inner core and the outer rim could be dated and constrain different metamorphic stages. (f) Breakdown of allanite to monazite in a metapelite of the Central Alps, Switzerland. The distinct ages of allanite and monazite define a heating rate during collision of 8–15 °C/Ma

Uranium-Lead, Metamorphic Rocks, Fig. 1 (continued) (Janots et al. 2009). (g) Core-rim zoning in a titanite from a calcsilicate of the ultrahigh-pressure unit of Dora Maira, Western Alps, Italy. The core and rims formed at different pressure (HP and LP: high and low pressure), and their age defines a fast exhumation rate of 3.4 cm/year (Rubatto and Hermann 2001). Circles indicate the location of ion microprobe U–Pb analyses

techniques are carried out with scanning electron microscopes; they cause little or no damage to the sample and are relatively fast to acquire.

Materials

Minerals used for U–Pb dating in metamorphic rocks are numerous and include zircon (ZrSiO_4), monazite $[(\text{La}, \text{Ce}, \text{Nd}, \text{Th})\text{PO}_4]$, allanite $[(\text{Ca}, \text{REE}, \text{Th})_2(\text{Fe}^{2+}, \text{Al})_3\text{Si}_3\text{O}_{12}(\text{OH})]$, titanite (CaTiSiO_5), rutile (TiO_2), and, less commonly, baddeleyite (ZrO_2).

Zircon and monazite are the most commonly dated U–Th minerals and offer specific advantages when dating metamorphism. Because the diffusion of Pb is particularly slow in these two minerals, they preserve their U–Pb formation age even if heated to high metamorphic temperatures (800–900 °C) or if the host rock is chemically altered. This allows zones in inherited zircons that have overgrowths formed during metamorphism to be separated from ones that grow during metamorphism. Additionally, both minerals commonly develop multiple growth zones that may preserve a record of more than one metamorphic stage (Fig. 1). Metamorphic zircons can form in a variety of conditions virtually covering all metamorphic grades, but are most common at high pressure (Rubatto and Hermann 2007) and/or high temperatures, particularly in the presence of melt (Rubatto et al. 2001). Dating of metamorphic zircon has shed light on the age of metamorphism from the earliest records of plate tectonic (Friend and Nutman 2005) to the youngest exhumed eclogites (Baldwin et al. 2004). Unlike other U–Th minerals, zircon commonly preserves a record of the pre-metamorphic history, be it magmatic or sedimentary. Metamorphic growth zones can be distinguished on the basis of their zoning and composition. Zoning is most commonly weak and/or not polygonal. A low Th/U content is typical of most metamorphic zircon because of coexisting phases like monazite or allanite sequester Th. The trace element composition of metamorphic zircon can also be diagnostic (see below and Hoskin and Schaltegger 2003). Another quality of metamorphic zircon is its physical robustness and capacity to act as a container of mineral inclusions (Fig. 1a). A challenging aspect of dating metamorphic zircon is that it may contain lower amount of U and Th than magmatic zircon and thus have weak radiogenic signal. This results in a high percentage of initial Pb and large analytical errors. Therefore, U–Pb analyses of metamorphic zircon are commonly plotted in uncorrected “Tera-Wasserburg” diagrams, where the age is determined by the free regression of multiple data points (Fig. 2a).

Monazite is particularly appealing to date metamorphism because it has similar qualities to zircon, but is more reactive to metamorphism (Rubatto et al. 2001). It readily forms in metapelites (fine-grained metamorphosed sediments) and some metagranitoids (metamorphosed igneous aluminosilicate-rich rocks) from diagenesis to granulite facies and can preserve multiple growth zones of different age (Fig. 1d). It contains significant amounts of U and Th and both systems can be used for age determination.

Allanite is common in Ca-rich metamorphic rocks. Like monazite, it can preserve multiple metamorphic growth zones (Fig. 1e). Monazite and allanite both contain significant amounts of light rare earth elements and thus commonly show mutual replacement textures (Janots et al. 2008) that are valuable for age interpretation (Fig. 1f). Unlike most other U–Th minerals, allanite

Fig. 2 (a) Tera-Wasserburg diagram of ion microprobe (SHRIMP) analyses of very low U (1–6 ppm) zircon from an eclogite. The proportion of initial Pb in the analyses is between 15 % and 60 %. The date is given by the lower intercept of the regression line with the reverse Concordia curve. (b) Th–Pb isochron for LA-ICPMS analyses of metamorphic allanite. The isochron gives an accurate age despite the uncertainty on the composition of the initial Pb (Gregory et al. 2012). Pb_c denoted the non-radiogenic Pb component. Data are plotted with two sigma errors and average ages are given at 95 % confidence level

incorporates a significant amount of Pb during growth, particularly in sub-solidus metamorphic rocks (Gregory et al. 2012). This initial Pb can severely hamper the precision of U–Pb dating and requires a particular analytical treatment, such as independent measurement of initial Pb or Th–Pb isochrons (Fig. 2b). Because allanite contains more Th than U, the Th–Pb system is generally less contaminated by initial Pb and thus most reliable for age determination.

Rutile is an appealing mineral to date metamorphism because it mainly forms in metamorphic environments, most commonly in high pressure and temperature rocks, and it can be used as a thermometer (Zack et al. 2004). However, this oxide does not necessarily contain enough uranium – and no Th – and thus its radiogenic signal may be too weak to be measured accurately. The concentration of U in rutile is particularly low in mafic rocks (i.e., eclogites), whereas rutile in metasediments and granitoids can be richer in U, especially if metamorphosed at high temperature (Vry and Baker 2006; Kooijman et al. 2010; Ewing et al. 2013). Because rutile does not seem to preserve metamorphic growth stages, it is suitable for bulk dating by isotope dilution thermal ionization mass spectrometer (TIMS) that can achieve better precision. The diffusion of Pb in rutile and thus the potential to reset the radiogenic signal is relatively fast compared to the other U–Th-bearing minerals (Cherniak 2000; Kooijman et al. 2010). This makes rutile most suitable to date metamorphic stages below ~ 600 °C.

Titanite is a common U-bearing mineral in metamorphic rocks of variable composition. Its role as geochronometer is limited by low U and thus radiogenic Pb contents and high proportion of initial Pb (Romer 2001). As for rutile, titanite in mafic rocks is particularly difficult to date, and best results have been obtained for titanite in metasediments (Kohn and Corrie 2011), including metacarbonates (Rubatto and Hermann 2001).

Baddeleyite forms in silica-undersaturated rocks, i.e., mafic and ultramafic rocks free of quartz. It is commonly used to date mafic dikes, but can occasionally form during metamorphism (Rubatto and Scambelluri 2003). It shows internal zoning similar to zircon.

Fig. 3 Rare earth element patterns of U–Pb accessory minerals in different metamorphic assemblages. Patterns are normalized to chondrite values

Dating of Metamorphic Stages

The necessary connection between a measured U–Pb age and the metamorphic stage/reaction that such an age constrains can be achieved via different methods. Inclusions of metamorphic minerals in dated mineral zones can be a direct indication of when the dated mineral formed. For example, inclusion of high-pressure minerals, such as diamond (Fig. 1a) or coesite, in zircon indicates that the zircon formed above a certain pressure. Together with inclusion relationships, other textural relationships with main rock-forming minerals can be useful to determine at which metamorphic stage a U–Th mineral crystallized. However, because accessory minerals are often small in size and can be inherited to the metamorphic mineral assemblage, such relationships are not always straightforward.

Occasionally, the formation of U–Th minerals during metamorphism can be traced back to a specific reaction. Examples are formation of micro-zircons during garnet breakdown (Degeling et al. 2001), the reaction between allanite and monazite that involves other minerals (Fig. 1f) (Janots et al. 2008), and the rutile-titanite transformation. These are rare cases and most commonly U–Th minerals form by recrystallization or dissolution-precipitation of preexisting crystals.

Accessory mineral thermometry is another direct way to establish the temperature at which a dated mineral zoned formed. The Ti-in-zircon (Watson et al. 2006) and the Zr-in-rutile thermometers (Zack et al. 2004) are both based on the trace element composition (Ti and Zr respectively) of two minerals that can be dated by U–Pb. Because the diffusion of Zr and Ti is slow, these thermometers are robust up to extreme metamorphic temperatures. In metapelites containing monazite, xenotime (YPO₄), and garnet, the content of Y- and heavy-REE in monazite depends on temperature and can be used as a thermometer (Heinrich et al. 1997; Pyle et al. 2001).

The partitioning of trace elements between U–Th minerals and major rock-forming minerals can be used to link ages to specific assemblages. Most of the U–Th minerals are rich in trace elements, particularly yttrium and rare earth elements (REE, Fig. 3). Their Y-REE composition depends on the composition of the rock and the abundance of other coexisting minerals that contain significant amounts of such elements, including garnet for Y- and heavy-REE and feldspar for europium and strontium. For this reason, variation in trace element contents and specific REE patterns are typical

of certain assemblages (Fig. 3). Zircon that forms at high pressure develops a REE signature particularly low in heavy-REE and with no Eu anomaly (Rubatto 2002). Zircon in granulites is relatively depleted in heavy-REE and has a strong negative Eu anomaly due to coexistence with abundant garnet and feldspars. Similarly monazite that has grown in a garnet-rich assemblage will have a particularly strong depletion in heavy-REE. High-pressure monazite, that has grown in a feldspar-free assemblage, is also rich in Sr (Finger and Krenn 2007). This approach is particularly powerful if variations in trace element composition are seen in distinct growth zone of the same crystal (Hermann and Rubatto 2003; Xia et al. 2009; Rubatto et al. 2013).

Conclusions and Future Prospectives

Our ability to date U–Th minerals in metamorphic rocks is currently limited by the capacity to sample small growth zones and measure their age with high precision. In the future, further developments of micro-sampling using microbeam techniques, as well as increased analytical sensitivity and precision for very small sample volumes and low radiogenic samples, will greatly benefit U–Pb dating of metamorphism.

The interpretation of ages in terms of rock evolution (pressure, temperature, fluids, and deformation) is the other limiting factor. The discovery of new geothermometers and geobarometers based on U–Th minerals would make a significant difference in our capacity to constrain the time of metamorphic stages. Similarly, advances in the understanding of the petrological behavior of such minerals and improvements in the thermodynamic modeling of their P–T stability would greatly assist age interpretation.

Amino Acid Racemization, Marine Sediments

Darrell Kaufman*

School of Earth Sciences and Environmental Sustainability, Northern Arizona University, Flagstaff, AZ, USA

Definition

Amino acid racemization. The phenomenon of conversion of “left-handed” (L or “levo”) amino acids to their “right-handed” (D or “dextro”) form. In most living systems, 100 % of the amino acids are of the L form, and the conversion results in an equal mixture of D and L when the racemization reaction is complete.

Marine Sediment. Material that accumulates in the marine environment. This article focuses on material collected in cores from deep-sea settings.

Among the wide range of applications of amino acid geochronology, this technique is especially well suited for dating deep-sea sediments using foraminifera. Foraminifera inhabit most of the World Ocean and they contain relatively high concentrations of amino acids that are well retained by their carbonate test. The stable thermal environment of deep-sea sites minimizes the often-complicating effect of variable temperature on the long-term rate of racemization. Some of the earliest research on amino acid geochronology took advantage of the long-term stability of deep-sea settings to investigate the diagenesis of amino acids over geologic time, including the rate of racemization in foraminifera (Wehmiller and Hare 1971; Bada and Schroeder 1972; King and Hare 1972; Kvenvolden et al. 1973; Schroeder and Bada 1977; Bada et al. 1978; Bada and Man 1980; King 1980; Belknap and Doyle 1986; Stathopulos et al. 1987; Robbins and Brew 1990). The extent of amino acid racemization in fossil foraminifera has also been used to estimate the ages of Quaternary marine sediment (Müller 1984; Macko and Aksu 1986; Sejrup and Hughen 1992; Knudsen and Sejrup 1993; Murray-Wallace and Belperio 1994; Harada et al. 1996), and in a few cases, to reconstruct paleotemperature histories (Bada and Man 1980; Lehman et al. 1988; Johnson et al. 1990).

Two general approaches can be used to convert the extent of amino acid racemization to a numeric time scale: In the first approach, the effects of time and temperature on the extent of racemization are determined in modern shells subjected to high-temperature laboratory experiments (e.g., Kaufman 2006). This relation, together with a model of racemization kinetics, is used to calculate the age of a sample if its temperature history is known. Because accelerating the rate of racemization under high temperature may not precisely mimic the net effect of long-term diagenetic processes, most attempts to quantify the temperature sensitivity of long-term racemization extend their analyses to ambient temperatures and geologic environments by including analyses of Holocene samples whose ages are known from radiocarbon dating, and whose temperature history can be reasonably inferred from instrumental measurements. A more secure approach that does not require assumptions about temperature history is to calibrate the rate of racemization by analyzing securely dated samples of a particular taxon from a region where temperature histories are uniform (Sejrup et al. 1984; Harada and Handa 1995; Hearty et al. 2004; Kaufman et al. 2008, 2013). The calibrated reaction rate is then used to date samples of the same taxon of unknown age from the same environment where temperature histories are similar.

Figure 1 shows the extent of aspartic acid racemization (Asp D/L) in independently dated, mono-specific foraminifera samples from the Pacific, Atlantic, and Arctic oceans (Kaufman et al. 2013). These data

*Email: darrell.kaufman@nau.edu

provide the basis for developing a calibrated age equation to apply to undated samples (the second approach described above). Figure 1 also shows the modeled rate of racemization based on laboratory-heated and radiocarbon-dated foraminifera for three temperatures (Kaufman 2006). The ages of samples can be determined by analyzing their D/L values and assuming a reasonable temperature history (the first approach).

Most studies of amino acid geochronology based on foraminifera have used gas chromatography or ion-exchange HPLC to separate the D- and L-amino acids, both of which require hundreds of foraminifera tests for a single analysis (several milligrams of fossils). Consequently, these studies relied on samples of mixed foraminiferal taxa. Sample size requirements using HPLC reverse-phase chromatography (RPC) are at least two orders of magnitude lower (Kaufman and Manley 1998), allowing analysis of fewer, and even single specimens in the case of a taxon with a large test (Hearty et al. 2004). Subdividing a sample into small subsamples, each analyzed individually, can improve the accuracy of the results because collections of microfossils commonly include a few individuals whose D/L values fall outside the mean of the others. These outliers might result from post-depositional reworking, post-collection contamination, or an aberrant diagenetic pathway. Regardless of the cause, by routinely analyzing multiple subsamples per level (10 or more), these aberrant results can be identified objectively and excluded from the data set. The resulting mean D/L values are more accurate than those based on just a few subsamples.

The rate of racemization differs among foraminifera taxa. An early investigation of mono-specific samples (King and Neville 1977) showed that the extent of racemization (epimerization of isoleucine) in different taxa from the same level within a sediment core could differ by as much as a factor of 4 between species. More recent analyses based on the same approach and augmented by laboratory heating experiments do not show a difference of this magnitude among mono-specific samples, either as fossils or as laboratory-heated specimens (Kaufman et al. 2013). Differences in racemization rates might be

Fig. 1 Extent of racemization (D/L) for aspartic acid (*Asp*) in independently dated samples of all 179 mono-specific foraminifera samples from deep-sea cores in the Pacific, Atlantic, and Arctic oceans extending back to 1.5 Ma (Kaufman et al. 2013). Colors indicate the current site temperature grouped into four categories. In addition, the modeled rate of racemization based on laboratory-heated and radiocarbon-dated *P. obliquiloculata* for three temperatures is shown for comparison (dashed lines; Kaufman 2006). Data are plotted on logarithmic scales to improve data presentation

attributed to the effect of contamination of the type described by Stathoplos and Hare (1993) and Sejrup and Haugen (1992) and that can be recognized by the relatively high serine content (Kaufman et al. 2013).

Previous studies recognized the potential of exogenous amino acids to contaminate foraminifera and to skew the results (Stathoplos and Hare 1993; Sejrup and Huguen 1992). Many studies have investigated the procedures for pretreating samples to isolate the most reliably indigenous amino acid fraction (e.g., Penkman et al. 2008), and for applying data-screening criteria to identify and exclude outliers based on statistical tests of internal consistency among multiple amino acids (e.g., Kosnik and Kaufman 2008). In addition, the concentration of serine, a liable amino acid that is present in only low concentrations in fossils, has been used widely as an indicator of contamination by young amino acids (e.g., Kaufman et al. 2013).

Definition

Utilization of the rhenium–osmium (Re–Os) radioisotope geochronometer to (1) determine the depositional age of organic-rich rocks (ORR), (2) establish the Os isotope ($^{187}\text{Os}/^{188}\text{Os}$) composition of sedimentary successions, and (3) date the timing of hydrocarbon (oil) generation related to thermal maturation of an organic-rich sedimentary rock.

Introduction

The first application of the Re–Os isotope geochronometer to ORR demonstrated that the Re–Os data, although imprecise, could yield the depositional age of sedimentary successions (Ravizza and Turekian 1989), a remarkable outcome given the analytical challenges and data uncertainties at the time. Today, utilizing new analytical and mass spectrometry techniques (see below) and the most accurate ^{187}Re decay constant ($1.666 \times 10^{-11} \text{ year}^{-1}$; Smoliar et al. 1996) has permitted the determination of precise (in some cases $\leq 1\%$ uncertainty) depositional ages for ORR that possess $\geq 0.5 \text{ wt\%}$ total organic carbon (TOC) (e.g., Cohen et al. 1999; Georgiev et al. 2011; Kendall et al. 2009a; Selby and Creaser 2005a; Xu et al. 2009; Cumming et al. 2012). These studies have provided the foundation to apply the Re–Os organic-rich sedimentary rock geochronometer to yield ages throughout geological time for stratigraphic boundary intervals and major Earth events (e.g., rise of oxygen, Proterozoic glaciations etc.; Selby and Creaser 2005a; Selby 2007; Anbar et al. 2007; Xu et al. 2009; Rooney et al. 2011; Yang et al. 2009).

Rhenium–osmium geochronology of ORR utilizes the isochron method, which yields the initial Os isotope composition ($^{187}\text{Os}/^{188}\text{Os}$) for the sampled unit, taken to represent the $^{187}\text{Os}/^{188}\text{Os}$ composition of the water column at the time of deposition (Ravizza and Turekian 1989; Cohen et al. 1999; Peucker-Ehrenbrink and Ravizza 2000, 2012).

In addition to ORR, hydrocarbon products of such matured rocks, for example, crude oil and bitumen, have been shown to also be enriched in both Re and Os at the ppb and ppt level, respectively (Barre et al. 1995; Woodland et al. 2001; Selby and Creaser 2005b; Selby et al. 2007; Finlay et al. 2011). The hydrocarbon Re–Os isotope data from several petroleum systems has shown that Re–Os systematics of hydrocarbons can provide the timing of petroleum generation from an oil source rock (Selby et al. 2005; Selby and Creaser 2005b; Finlay et al. 2011), with the initial $^{187}\text{Os}/^{188}\text{Os}$ value derived from Re–Os hydrocarbon data interpreted to reflect the $^{187}\text{Os}/^{188}\text{Os}$ inherited from the source rock at the time of petroleum expulsion (Selby and Creaser 2005b; Rooney et al. 2012).

Methodology: Analytical Protocol and Sampling

Since the pioneering application of the Re–Os chronometer to dating of ORS (Ravizza and Turkeian 1989), significant analytical advancements in digestion methods, chemical purification, and mass spectrometry have permitted the determination of precise Re–Os data. Current methods employ analysis of an aliquot of ground organic-rich rock digested in either inverse aqua regia (3:6 ml mix of concentrated HCl:HNO₃) or 8 ml of 4 N H₂SO₄ with 0.25 g/g CrO₃ along with a known amount of isotope tracer solution (¹⁸⁵Re + ¹⁹⁰Os) in a Carius tube at 220°C for 48 h (Cohen et al. 1999; Selby and Creaser 2003). The use of the Cr^{VI}–H₂SO₄ digestion method has been shown to limit the release of detrital Re and Os from organic-rich rock matrices and as a result reduce the scatter about the line of an isochron (Selby and Creaser 2003; Kendall et al. 2004). The inverse aqua regia medium is used for the digestion of hydrocarbons, such as asphaltene and bitumen. Osmium from the acidic solution is typically isolated and purified by solvent extraction (CCl₄ or CHCl₃) and microdistillation (Cohen et al. 1999; Selby and Creaser 2003; Selby et al. 2007). The Os extracted acidic solution is then used to isolate and purify the Re fraction of the sample. This is achieved by solvent extraction methods and anion chromatography (Selby and Creaser 2003; Chen et al. 2010). The isotope compositions of the purified Re and Os fractions are commonly determined by negative thermal ionization mass spectrometry (Creaser et al. 2002 and references therein).

Re–Os organic-rich rock geochronology requires samples that have not been significantly affected by postdepositional processes such as weathering (Peucker-Ehrenbrink and Hannigan 2000), metamorphism (above greenschist grade; Kendall et al. 2004), and hydrothermal fluid flow (Kendall et al. 2009b; Rooney et al. 2011), in order to minimize any postdepositional mobilization of Re and Os (Kendall et al. 2009a). The application of the isochron method for geochronology requires two principal criteria: (1) the sample set possesses the same or near-identical initial ¹⁸⁷Os/¹⁸⁸Os, but has varied parent/daughter ratios (¹⁸⁷Re/¹⁸⁸Os), and (2) the isotope systematics is not disturbed. At this time, there is no proxy to determine if a section will have both homogeneous initial ¹⁸⁷Os/¹⁸⁸Os and variable ¹⁸⁷Re/¹⁸⁸Os (cf. Turgeon et al. 2007; Cumming et al. 2012). A review of sampling protocols employed in various studies suggests intervals ranging from a few centimeters to several meters can be used to produce precise ages, with at least 20 g of powdered sample required to achieve sample Re–Os homogeneity (cf. Creaser et al. 2002; Kendall et al. 2009a).

Hydrocarbon Re–Os geochronology analysis utilizes either the asphaltene isolated from crude oil or bitumen (Selby et al. 2007). To date, sampling from wells across an oil field has provided Re–Os data sets that have given valuable age information to determine the timing of hydrocarbon generation (Selby et al. 2005; Selby and Creaser 2005b; Finlay et al. 2011; Lillis and Selby 2013).

Organic-Rich Rocks: Rhenium–Osmium Geochronology and Systematics

Rhenium and Os are organophilic, enabling the uptake of hydrogenous Re and Os into organic matter during deposition of ORS (Ravizza and Turekian 1989; Cohen et al. 1999; Selby and Creaser 2003). The Re and Os concentrations in marine and lacustrine ORS range from average upper-crustal abundances (0.2–1 ppb Re and 30–50 ppt Os; e.g., Peucker-Ehrenbrink and Jahn 2001) to several hundred ppb/ppt of Re and Os, respectively (e.g., Baioumy et al. 2011; Cohen et al. 1999; Creaser et al. 2008; Georgiev et al. 2011; Rooney et al. 2010; 2011; Poirier and Hillaire-Marcel 2011; Cumming et al. 2012). Although organophilic, Re and Os abundances do not always

correlate to TOC despite the majority of these metals being held within the kerogen (Rooney et al. 2010, 2012; Cumming et al. 2012).

From the first Re–Os ORR study (Ravizza and Turekian 1989), numerous studies have reported accurate and precise Re–Os depositional ages of organic-rich marine and lacustrine sedimentary units (e.g., Cohen et al. 1999; Creaser et al. 2002; Cumming et al. 2012; Turgeon et al. 2007; Rooney et al. 2011; Xu et al. 2009). Studies also indicate that hydrocarbon maturation and/or low-grade metamorphism does not appreciably disturb the Re–Os systematics (Kendall et al. 2004; Rooney et al. 2010, 2011, 2012; Yang et al. 2009). In contrast to studies yielding highly precise Re–Os ages, the Re–Os data for the Aptian/Albian, Cenomanian/Turonian, and Frasnian–Famennian stage boundaries give accurate, but imprecise ages (Turgeon et al. 2007; Selby et al. 2009). This imprecision is attributed to the limited spread in $^{187}\text{Re}/^{188}\text{Os}$ ratios, highlighting the need for variation in $^{187}\text{Re}/^{188}\text{Os}$ ratios but no variation in initial $^{187}\text{Os}/^{188}\text{Os}$ to produce precise Re–Os dates. The lack of spread is considered to be due to exhaustion of the Re reservoir due to increasing anoxia leading up to the Frasnian–Famennian boundary (Turgeon et al. 2007). However, no correlation is evident between redox conditions and $^{187}\text{Re}/^{188}\text{Os}$ values of ORS (Selby et al. 2009). Alternatively, organic matter type may control Re–Os fractionation in ORS (Cumming et al. 2012; Harris 2012).

Rhenium–Osmium Hydrocarbon Geochronology and Systematics

Petroleum exploration is often hampered by the lack of spatial and temporal controls on hydrocarbon formation. Traditionally, dating the timing of hydrocarbon generation involves basin modeling using estimated parameters (e.g., Ruble et al. 2001). Therefore, knowing the absolute age of petroleum generation provides vital constraints for elucidating petroleum maturation and migration. A pioneering study (Selby et al. 2005) provided evidence of the ability of the Re–Os hydrocarbon geochronometer by yielding an accurate age for bitumen (374.9 ± 9 Ma) from the Polaris Mississippi-Valley-type deposit, Canada, that was in agreement with paleomagnetic and Rb–Sr sphalerite age constraints for mineralization. Further to this, the Re–Os geochronometer has also been applied to the tar sands of the Western Canadian Sedimentary Basin and provided an accurate age (112 ± 5.3 Ma) for the timing of hydrocarbon generation, suggesting that Re–Os hydrocarbon geochronology records the age of oil generation (Selby and Creaser 2005b). A subsequent Re–Os study of oils from the UK Atlantic margin oil fields provided a Re–Os generation age of 68 ± 13 Ma that agrees with basin models and Ar–Ar ages for K-feldspars bearing oil-rich fluid inclusions and demonstrated that the Re–Os hydrocarbon systematics is unaffected by biodegradation (Finlay et al. 2011).

Both Re and Os in hydrocarbons have been shown to be held in the heavy molecular fraction of oil (asphaltene) and suggested to reside within metalloporphyrins similar to Ni and V or heteroatomic ligands due to their abundance in asphaltene. The asphaltene fraction is shown to possess the same isotopic compositions to that of the whole oil. This study advanced the analytical application of this tool as the separation of asphaltene for Re–Os analysis allows much higher abundances to be analyzed, yielding more precise Re–Os data (Selby et al. 2007).

Oil-to-source correlation is most commonly carried out by using carbon isotopes and/or biomarkers, but these methods can be hampered by biodegradation as they rely on the light fractions of oil that are removed by biodegradation (Peters et al. 2005). The initial $^{187}\text{Os}/^{188}\text{Os}$ value derived from the Re–Os hydrocarbon data is interpreted to reflect the $^{187}\text{Os}/^{188}\text{Os}$ inherited from the source rock at the time of petroleum expulsion (Selby and Creaser 2005b; Selby et al. 2005, 2007; Finlay

et al. 2011, 2012). The reliability of Os as an oil-to-source fingerprinting tool was further corroborated experimentally (Rooney et al. 2012). This involved artificial maturation of the source rocks coupled with Re–Os analysis of the original rocks and the products derived from the hydrous pyrolysis experiments in order to assess transfer of Re and Os from source to oil. The $^{187}\text{Os}/^{188}\text{Os}$ compositions in bitumens were found to be the same as their source rock in both units studied, providing strong evidence that Os isotopes can be used as powerful oil-source correlation tools.

Although the petroleum Re–Os systematics is not appreciably disturbed, biodegradation studies have indicated that the systematics can be affected by the interaction of mantle fluids (Finlay et al. 2011) and TSR (Lillis and Selby 2013). These studies demonstrated the importance of Os in understanding crustal-scale fluid dynamics, oil migration pathways, and Re–Os hydrocarbon systematics.

Summary

Rhenium–osmium analysis of marine and/or lacustrine ORR permits the age of deposition of the sediment to be established. This method also yields the osmium isotope composition of the water column associated with the deposition of the sediment. The Re–Os systematics of ORR is not disturbed by processes associated with oil generation and/or low-grade metamorphism. Rhenium–osmium analysis of oil generated and migrated from ORR has been shown to yield the timing of hydrocarbon maturation. Further the petroleum Os isotope data have been shown to be a potentially powerful tool to aid in fingerprinting an oil-to-source ORR.

Molecular Dating of Evolutionary Events

David Duchene* and Lindell Bromham

Centre for Macroevolution and Macroecology, Division of Evolution, Ecology, and Genetics, Research School of Biology, Australian National University, Canberra, ACT, Australia

Definition

Inference of the age of evolutionary events using statistical analysis of rates of change of DNA or amino acid sequences.

Introduction

Molecular dating is used in the biological sciences to estimate the age of evolutionary events. Changes to DNA and amino acid sequences accumulate continuously in the genome over time, so comparing DNA sequences between lineages allows us to estimate the time since they last shared a common ancestor. However, the rate of change varies across the genome and among species. So in order to use molecular data to date evolutionary events, we need a way of estimating the rate of change in genetic sequences over time for any given dataset. Molecular dating requires a set of homologous genetic sequences (all related by descent from a single ancestral sequence), a method for inferring the number of changes that have occurred during the evolution of these sequences, and calibrating information to estimate their rate of change.

An increasing variety of analytical tools are available for molecular dating of evolutionary events. All assume that the rate of genetic sequence evolution has some degree of predictability, so that the age of lineage divergence can be estimated from molecular data using a model of evolutionary change and some information about timing of evolutionary events (typically derived from fossils, biogeography, pedigree, or ancestral genetic sequences).

Methods for Dating Evolutionary Events

Molecular dating methods begin by estimating the amount of genetic difference that has occurred between sequences. Then, assumptions about the rate of change are used to infer the amount of time needed to explain that amount of genetic difference. The difference between genetic sequences is estimated using a model of the frequency of each type of substitution. Models of molecular evolution form the basis of methods to estimate the relatedness of multiple sequences and the timing since their evolutionary divergence (for more detail on the models, see Yang 2006). These models can be simple and give an equal probability to every type of substitution (Jukes and Cantor 1969), or be complex and account for the attributes of specific genetic datasets (e.g., Yang 1994). For instance, the mitochondrial ND6 genetic region in marine mammals has virtually no transversions (changes from the purines, A and G, to pyrimidines, C and T, or vice versa), so it

*Email: david.duchene@anu.edu.au

is appropriate to use parameter settings that model a large number of transitions (changes from purine to another purine, or pyrimidine to pyrimidine) (Duchêne et al. 2011).

The simplest way to use genetic difference estimates to infer the timing of evolutionary divergences is to select “clocklike” data, where the amount of genetic difference accumulates at the same rate in all lineages. There are methods to detect significant variation in rates (Langley and Fitch 1973; Takezaki et al. 1995). For example, Likelihood Ratio Test can be used to ask whether data can be best described by a single uniform rate, or a multiple rate model (Brown and Yang 2011). Importantly, while some datasets may approximate uniform rates, clocklike behavior cannot be generalized to a particular gene, lineage, or taxonomic level.

Another way to account for rate variation is to have multiple rate categories in the same analysis. For example, sections of the dataset may have their own “local clock” (Drummond and Suchard 2010; Rambaut and Bromham 1998; Yoder and Yang 2000). Other methods account for rate variation by “relaxing” the molecular clock constraint on all branches, so every branch in a phylogeny has a different rate (e.g., Drummond et al. 2006; Yang 2007); for more on this topic, see Springer Reference article Relaxed Molecular Clocks; for reviews on dating methods, (see Magallón 2004; Rutschmann 2006; Welch and Bromham 2005).

Calibrating the Rate of Substitutions

Some molecular dating analyses use an assumed rate of substitutions to estimate dates. However, given that rates of molecular evolution vary across the genome and between lineages, it is preferable to use independent information to calibrate rates of molecular evolution for each dataset analyzed. The most common way of calibrating rates is to use a known date of one or more divergence events in the phylogeny.

The calibration must correspond to the earliest possible age of a node in the phylogeny. The dates of divergence events are rarely known with certainty, and the confidence limits on calibrations can be very large. In the case of fossil evidence, part of the uncertainty comes from the determination of the age of the fossil itself, drawn from stratigraphy and isotopic composition of the fossil (Benton and Donoghue 2007). However, the exact relationship between the fossil taxon and the divergence in the phylogeny is also typically unknown (Sauquet et al. 2012). A fossil taxon is unlikely to be identifiable as a member of a particular lineage until some time after the origin of the lineage, when key diagnostic characters have had time to evolve. So fossil dates typically represent minimum ages of lineages: they provide evidence that a lineage must have originated some time before that date (Bromham et al. 1999).

One way to account for calibration uncertainty is to have a probability distribution of node ages. A hard-bound can define the latest or the earliest point where a divergence may have occurred (also called the minimum age and the maximum age, respectively). While a minimum age can be defined by the age of a fossil known to occur on the lineage in question, because the lineages must have originated before the occurrence of the first fossil, special caution is required when placing a maximum constraint because it assumes with total confidence that a lineage was absent before a given time (Benton and Donoghue 2007; Ho and Phillips 2009; Hug and Roger 2007).

To overcome the strict assumptions of hard-bounded calibrations, an alternative is to use soft-bounded calibrations, so a nonzero probability can be assigned to all ages (Yang and Rannala 2006). To define a soft-bounded calibration, the user must specify a probability distribution for the date of the calibrating divergence. Given that the confidence in particular date estimates is specific to current knowledge, expert advice is often required to define these calibrations. Broadly,

a normally distributed calibration is conservative for fossil data that is imprecise or equivocal. A normally distributed calibration can also be used for biogeographic data that provides reasonable evidence for causing a divergence event, or for calibrations based on previous date estimation analyses (also called secondary calibrations, Ho and Phillips 2009). Lognormal distributions are often appropriate for fossil data as they provide a hard minimum bound, which is the age of the fossil. They also allow a higher probability for the divergence of a node at a point slightly older than the age of the fossil. These distributions are also applied when using previous date estimates from Bayesian analyses that produced lognormal distributions.

Exponentially distributed calibrations can be used if there is little evidence that an event occurred at any point before the fossil, or if the fossil is likely to be very close to the divergence event (Ho and Phillips 2009). To choose the values of the parameters of these distributions, the user must be well informed about the sources of error in the calibration. Poor calibrations may be useful if their uncertainty can be quantified, but if only poor calibrations are used, then the uncertainty in date estimates will be significant.

Summary and Conclusions

The field of molecular dating of evolutionary events can be divided by the methods to deal with variation in the rate of molecular substitutions. To date evolutionary events using molecular data, it is necessary to evaluate and choose a method to model molecular evolution. It is also necessary to find information to calibrate rates of substitutions, and all analyses must account for calibration uncertainty. Although modern software for this purpose can be deceptively simple, there is a plethora of considerations required before performing molecular dating analyses. In particular, Bayesian methods for molecular dating can involve complex assumptions about the model of molecular evolution and arguably are not entirely understood. Methods in place to compare and choose the most appropriate dating schemes are computationally demanding and may be severely biased (Baele et al. 2012; Lartillot and Philippe 2006; Xie et al. 2011). However, with appropriate information and a clear understanding of the uncertainty inherent in molecular date estimates, molecular dating is a powerful tool that can be extended to study the realms of evolution, ecology, biogeography, and past population processes.

Synonyms

[Chronostratigraphy](#); [Stratigraphic correlation using tephra](#); [Tephrostratigraphy](#)

Definitions

Tephra. All the explosively erupted, unconsolidated pyroclastic products of a volcanic eruption.

Cryptotephra. Tephra-derived glass-shard and/or crystal concentration preserved in sediments or soils/paleosols but not visible as a layer to the naked eye.

Tephrostratigraphy. Study of sequences of tephra layers or cryptotephra (and associated deposits) and their lithologies, spatial distribution, stratigraphic relationships, and relative and numerical ages. Involves defining, describing, characterizing, and dating tephra layers or cryptotephra deposits in the field and laboratory as a basis for their correlation.

Tephrochronometry. Obtaining a numerical age or calendrical date for a tephra or cryptotephra deposit.

Tephrochronology sensu stricto. The use of primary tephra layers or cryptotephra as isochrons to connect and synchronize depositional sequences, or soils, and to transfer relative or numerical ages to the sequences using lithostratigraphic, compositional, and other data pertaining to the tephras/cryptotephra.

Tephrochronology sensu lato. All aspects of tephra/cryptotephra studies and their application.

Introduction and Definitions

Tephras are the explosively erupted, unconsolidated pyroclastic (fragmental) products of a volcanic eruption (Greek *tephra*, “ashes”) (Lowe 2011). Typically they comprise volcanic glass (including shards, pumice, and scoriae or cinders), rock (lithic) fragments, and crystals (mineral grains), which are erupted through the atmosphere and deposited on the land, the seafloor, or ice caps relatively quickly – usually in a matter of hours or days according to eruption duration (Lowe 2011; Stevenson et al. 2012). A tephra layer deposited from a powerful eruption, and not reworked, consequently forms a widespread, thin blanket on the surface of the Earth that has effectively the same age – an isochron – wherever it occurs. The term “tephra” encompasses all grain sizes: ash (grains <2 mm in diameter), lapilli (64–2 mm), or blocks (angular) or bombs (rounded) (>64 mm) (White and Houghton 2006). Diminutive, distal tephras that are not visible as layers in the field are called cryptotephra (Greek *kryptein*, “to hide”). Cryptotephra comprise concentrations of ash-sized glass

*Email: d.lowe@waikato.ac.nz

Fig. 1 Stratigraphic sequence of four Holocene tephra deposits of ash and lapilli grade, and buried soil horizons, near Mt Tarawera, New Zealand. Exposure is ~2 m high. From *top*, Tarawera tephra (mainly Rotomahana Mud member) (erupted 10 June 1886); shower-bedded Kaharoa tephra ($AD\ 1314 \pm 12$), characterized by abundant biotite; Taupo tephra ($AD\ 232 \pm 10$) (note that the *gray* and *dark-brown* soil horizons evident in the upper part of the nonwelded Taupo deposit, Taupo ignimbrite, are the result of podzolization, an acidic soil-leaching process that occurred here prior to the soil's burial by the Kaharoa eruptives); and Whakatane tephra ($5,526 \pm 145$ cal. year BP) (ages from Lowe et al. 2013) (Photo: Megan Balks)

shards or crystals, or both, usually $<150\ \mu\text{m}$ in diameter, preserved in sediments (including ice), in cave deposits, or in soils or paleosols (Lowe 2011; Lane et al. 2014).

Tephrochronology may be defined as the use of primary tephra layers or cryptotephra deposits as isochronous beds to connect and synchronize depositional sequences and to transfer relative or numerical ages (or dates) to such sequences using stratigraphic information together with lithological, compositional, and geochronological data obtained for the tephtras or cryptotephtras. Tephrochronology is thus a method for correlating and dating geological, paleoecological, paleoclimatic, or archaeological sequences or events, or soils, using characterized tephtras or cryptotephtras as chronostratigraphic marker beds (Alloway et al. 2013).

Tephrochronology is undertaken typically in three steps. Firstly, tephra deposits are correlated from place to place in the field using their lithostratigraphic and relative age relationships along with intrinsic physical properties, associations with other deposits, and spatial distribution, i.e., tephrostratigraphy (Fig. 1). Fieldwork is carried out at a range of scales because tephra deposits become thinner, and constituent components become smaller, from proximal to distal locations. A potential complication is tephra remobilization, which is discussed later. Secondly, the components of the deposits are characterized or “fingerprinted” using mineralogical or geochemical analytical methods, often both, in the laboratory to aid their correlation. Such laboratory characterization is essential in cryptotephra studies. Thirdly, when a numerical age or date for a tephra or cryptotephra deposit is obtained, i.e., tephrochronometry, that age or date can be transferred from

one site to the next by comparing the compositional characteristics or “fingerprints” of its components with those of equivalent deposits elsewhere. These three steps – (i) mapping tephra and determining their lithostratigraphic relationships, (ii) characterizing tephra/cryptotephra in the laboratory, and (iii) dating them – enable tephrochronology to function as a unique stratigraphic and geoscientific dating tool and are described below in detail after a subsection on volcanological applications.

Volcanological Applications of Tephrochronology

As well as providing isochrons for geological, archaeological, and paleoenvironmental applications, tephrochronological studies involving mapping, characterization, and dating are critical for developing a comprehensive record of past explosive eruptions and recurrence rates from which time-space relationships of volcanism can be established and volcanic hazards evaluated (e.g., Óladóttir et al. 2008; Kuehn and Negrini 2010). Knowledge of the distribution and thickness relationships of tephra or cryptotephra deposits enables magma volumes to be calculated (Wilson et al. 2009; Ponomareva et al. 2013a). Near to volcanic centers, deposits may include lavas as well as an array of different types of pyroclastic deposits (fall, surge, flow and density current, and explosion breccias; Fig. 2), and detailed studies of their stratigraphic intercalation and physical, mineralogical, and geochemical properties provide insight into volcanic history and petrogenesis (e.g., Ponomareva et al. 2004; Smith et al. 2005; Turner et al. 2011a; Cioni et al. 2014). Information about the release of volatiles into the atmosphere and associated climatic impacts can also be gleaned from studies on tephra (e.g., Zdanowicz et al. 1999; Alloway et al. 2013; Sigl et al. 2013).

Mapping and Correlating Tephra

The most successful approaches in the field include the so-called hand-over-hand method whereby relatively thick sequences of tephra, typically meter to decimeter scale, at proximal or medial locations, are documented and traced from one outcrop or section to the next using distinctive physical properties in combination with their stratigraphic associations (Fig. 3). Physical properties include color, bedding characteristics, or particle-specific features such as pumice/scoria, lithic, and crystal componentry, the presence of accretionary lapilli, or marker mineral grains (crystals) such as biotite identifiable via a hand lens. Distinctive marker beds provide a useful stratigraphic starting point in unraveling the complexities of geological sequences in road cuttings or natural exposures, and detailed lithostratigraphic columns are constructed to provide the basis essential for correlating from one site to the next (Fig. 3). The nature of buried soil horizons, or loess or other deposits associated with tephra layers, including (for example) fossils or other attendant paleoecological information such as pollen assemblages (e.g., Newnham and Lowe 1999; Housley et al. 2013; Westgate et al. 2013a), or archaeological relationships (Feibel 1999; Mullen 2012; Riede and Thastrup 2013), may provide additional contextual information helpful for affecting correlation (Fig. 4). High-resolution tephrostratigraphic records in Iceland were constructed by Streeter and Dugmore (2013) using digital photography to obtain thousands of stratigraphic measurements of multiple tephra layers intercalated with sediments at a resolution of 1 mm.

One potential difficulty in tephrostratigraphy arises where tephra remobilization has occurred or where glass shards or crystals have been disseminated or dispersed in sediments or soils, and hence primary isochron positions are not clear (Alloway et al. 2004a; Pyne-O'Donnell 2011; Housley et al. 2012). Remobilization of tephra resulting from widespread landscape instability in combination with climatic factors (e.g., Manville and Wilson 2004) can remobilize large volumes of tephra

Fig. 2 (a) Road section in the vicinity of Lago Blanco, Chaitén sector (42° S), southern Chile. The stratigraphy at this section reveals (from *top*) a prominent rhyolitic (c. 76 % SiO₂) pumiceous lapilli deposit (Cha-1 correlative) dated at c. 8,700 ¹⁴C year BP and sourced from an ancestral Chaitén volcano, closely overlying a rhyolitic (c. 71 % SiO₂) surge and fall couplet informally named Lepué tephra. This lower rhyolitic eruptive couplet, dated at c. 9,800 ¹⁴C year BP, is sourced from the nearby Michinmahuida Volcanic Complex (MVC). The buried soil horizon (“andic paleosol”) marks the hiatus between the Lepué and Cha-1 eruptions. (b) Low-angle cross-bedding and crosscutting relationship of the surge deposit across its co-eruptive fall deposit, Lepué tephra. (c) The Michinmahuida-sourced eruptive couplet is closely underlain by a widespread and distinctive layer of banded high-Si rhyolite breccia (indicated by *arrows*) that likely represents the products of an explosion of a pre-Cha-1 lava dome (ancestral Chaitén volcano). Such sections are particularly important in terms of recognizing eruptives with different field expression and composition, as well as for unraveling the complex and variable histories of closely situated (adjacent) eruptive centers (Photos: Brent Alloway)

for decades in the aftermath of a paroxysmal eruption (e.g., following the 1991 Pinatubo eruption; Torres et al. 2004). Remobilization of tephra can also be triggered by human activities (Swindles et al. 2013). Such reworked or disseminated tephra-derived constituents, including glass shards, form diachronous rather than isochronous surfaces, and hence their use as stratigraphic tie points is compromised unless remobilization is very localized or near contemporaneous with the primary depositional event. The non-reworked part of a tephra deposit provides an isochron of maximum age (the date of the tephra eruption and primary deposition), but any reworked components are younger (Lowe 2011).

Field correlation methods are increasingly limited as the tephra layers become thinner and finer with increasing distance away from source (e.g., Fig. 5), and the tephtras may become more irregularly distributed (e.g., Turney and Lowe 2001; Lawson et al. 2012). The tephtras typically lose diagnostic physical features (such as internal bedding) in subaerial sequences, and thin, separate beds can become mixed together by soil-forming processes or bioturbation, or by cryoturbation in periodically or perennially frozen landscapes (Sanborne et al. 2006; Lowe and Tonkin 2010;

Fig. 3 Stratigraphic columns and corresponding section photos detailing the tephrostratigraphy of deposits at two sites, Santa Barbara and Puerto Cardenas, in the Chaitén sector (42° S) of southern Chile. The tephra notation is from Naranjo and Stern (2004). A key tephra of interest is the prominent decimeter-thick gray tephra layer (Cor-1; now more recently and informally referred to as Lepu tephra) that contains conspicuous accretionary lapilli throughout. This tephra is the product of a large-scale phreatomagmatic eruption sourced from the glaciated Michinmahuida Volcanic Complex (MVC) dated at c. 9,800 ¹⁴C year BP. Tephra from the 2008 eruption of Chaitén volcano occurs on the present-day ground surface. Other strongly pedogenically weathered tephra beds represented within these sections have yet to be geochemically characterized and are probably variably sourced from other nearby volcanoes (Puyuhuapi, Melimoyu, Yanteles, and Corcovado). The tephra sequences at both localities rest on glacial till with a minimum age of c. 14,000 ¹⁴C year BP (Photos: Brent Alloway)

Fig. 4 Stratigraphy associated with hominin stone artifacts and vertebrate fossil remains from the So'a Basin, central Flores, Indonesia (unpublished data of B. V. Alloway, A. Brumm, G. van den Bergh, and R. Setiawan; after O'Sullivan et al. (2001) and Brumm et al. (2010)). The in situ stone artifacts occur immediately beneath a nonwelded (unconsolidated) ignimbrite deposit (Wolo Sege ignimbrite, WSI) that can readily be correlated and distinguished from other enveloping silicic tephra

Fig. 5 A distal occurrence of fine-grained Mazama tephra, 1–2 cm in thickness and composed mainly of glass shards, shows up as the pale “break” (where the person is touching) in an alluvium-soil sequence on the lowermost terrace alongside the North Saskatchewan River in Edmonton, Alberta, Canada. Multiple buried soils formed on intermittent flood deposits are evident in the section, with the high sedimentation (up-building) rate contributing to the rapid burial and preservation of the thin, fine-grained Mazama tephra as an inconspicuous layer. The Mazama tephra, dated at $7,627 \pm 150$ cal. year BP (Zdanowicz et al. 1999), provides a key isochronous time plane (chronostratigraphic marker bed) for Holocene archaeological and paleoenvironmental studies in the United States and southwestern Canada. Located ~1,450 km northeast of its source (Crater Lake, Oregon), the tephra was first identified here by Westgate et al. (1969) (Photo: David Lowe)

Dugmore and Newton 2012). Cores taken from lake sediments and peat bogs potentially provide a reliable means to record thin and/or fine-grained distal tephra layers, or at proximal or medial locations where tephras tend to be thicker and may have more restricted dispersal patterns around source vents – for example, in basaltic volcanic fields (Shane and Hoverd 2002). These lake or bog depositional environments allow thin tephras or glass-shard concentrations (cryptotephras) to be preserved amidst organic-bearing sediments (Fig. 6) (de Fontaine et al. 2007; Smith et al. 2013), notwithstanding potential taphonomic difficulties posed by tephra reworking or dispersion (Lowe 2011; Liu et al. 2014). Marine cores, especially from locations downwind of eruption centers, may also contain detailed records of tephra layers or cryptotephras intercalated with sediments (e.g., Guðmundsdóttir et al. 2012; Abbott et al. 2013; Ponomareva et al. 2013b; Austin et al. 2014).

Fig. 4 (continued) interbeds across the So’a Basin on the basis of its unique depositional architecture as well as its major-element glass-shard composition. The WSI, dated at 1.02 ± 0.02 Ma by $^{40}\text{Ar}/^{39}\text{Ar}$ (Brumm et al. 2010), provides important evidence for the presence of hominins on Flores for over 1 million years. (a) The base of WSI at the Wolo Sege section showing distinctive surge-like subunits containing accretionary lapilli and bedding consistent with the density segregation of entrained particles. Note the in situ bifacial flake in the paleosol immediately beneath the base of the WSI (indicated by arrow). (b) Close-up photo of the in situ bifacial flake identified at Wolo Sege. (c) In situ flaked core stone identified at the Matago section on the paleo-ground surface buried by the WSI. (d) Close-up photo showing the detail of the flaked core stone from the Matago section (Photos a–c: Brent Alloway; Photo d: Adam Brumm)

Fig. 6 Close-up of a near-basal part of a lake sediment core from Lake Okoroire, New Zealand, showing 3-cm-thick Rerewhakaaitu tephra, erupted $17,496 \pm 462$ cal. year BP from Mt Tarawera in the Okataina Volcanic Centre (Lowe et al. 2013; see Fig. 8 below). Many tiny *black specks* in the layer represent free biotite crystals diagnostic of this (and some other) tephtras derived from Mt Tarawera. Different sediment colors above and below the tephra reflect a climatically driven change from shrubland/grassland to forest in the region soon after the eruption (Newnham et al. 2003; Alloway et al. 2007). An indistinct uncorrelated tephra lies ~2 cm above the Rerewhakaaitu tephra. Scale marks in centimeters (Photo: David Lowe)

Possible reworking of tephtras (by currents, ice rafting, bioturbation) adds complexity in some cases (Brendryen et al. 2010; Larsen et al. 2014; Todd et al. 2014).

Together with those from lakes and bogs, many of the records of marine tephra deposits can thus document patterns of explosive volcanism in time and space and integrate the stratigraphic interfingering of eruptives from multiple volcanic sources (Shane et al. 2006; Swindles et al. 2011; Ponomareva et al. 2013a, b). Such compilations are often more comprehensive than those obtainable near volcanic centers because of burial or erosion of eruptives at such proximal locations, but an important caveat is that proximal deposits are typically more compositionally variable than distal deposits (e.g., Smith et al. 2005; Shane et al. 2008a). On this basis, distal deposits usually have a more restricted compositional range than otherwise might be generated during a particular eruptive episode.

Distal Tephtras and Cryptotephra Deposits

Submillimeter-scale studies have involved the development of new approaches to enable cryptotephtras, and very thin distal tephtras, to be mapped, albeit discontinuously, across landscapes using a range of methods firstly to *detect* and *isolate* glass-shard or crystal concentrations (e.g., Hall and Pilcher 2002; Gehrels et al. 2006; Swindles et al. 2010; Lane et al. 2014) and secondly to *correlate* them with known (previously characterized) deposits using geochemical analyses of glass shards, melt inclusions (glass) within crystals, or crystals (Matsu'ura et al. 2011; Swindles et al. 2013) as described below. Cryptotephtras have been discovered in peat, lake, marine, aeolian,

or frozen sediments or ice, in deposits in caves or rock shelters, and in soils or paleosols. They (and thin visible tephra) have been detected using ground-penetrating radar, magnetic susceptibility and remanent magnetization, X-radiography, X-ray fluorescence (including use of scanners), spectrophotometry, micro-petrography, enumeration of glass shards, and measurements of total organic carbon and loss on ignition (Turney and Lowe 2001; Gehrels et al. 2008; Lawson et al. 2012). These novel cryptotephra studies, although not without problems and limitations (e.g., Davies et al. 2007; Payne and Gehrels 2010; Swindles et al. 2011), have documented tephra-fall occurrences at submillimeter scales at distances of hundreds to some thousands of kilometers from source, greatly extending known geographical limits (e.g., Payne et al. 2008; Davies et al. 2010, 2012; Balascio et al. 2011). Pyne-O'Donnell et al. (2012) showed that “ultra-distal” cryptotephra derived from Holocene eruptions in Alaska and the Pacific Northwest occur ~7,000 km from source in eastern-most North America and one tephra, the Alaskan White River Ash (eastern lobe, erupted around AD 860), occurs ~16,000 km away in Ireland (Jensen et al. 2014). Lane et al. (2013) identified the c. 75,000-year-old Youngest Toba Tuff tephra as a cryptotephra deposit in Lake Malawi sediments in east Africa, >7,000 km west of the source volcano in Sumatra. Cryptotephra associated with the eruption of the Campanian Ignimbrite in Italy c. 40,000 calendar (cal.) year BP was identified across much of central Europe and the Mediterranean area by Lowe et al. (2012). As noted earlier with regard to visible tephra deposits, cryptotephra studies can help also in elucidating the eruptive history of volcanoes (e.g., Shane et al. 2013).

Ice cores provide detailed and valuable records of volcanism (Davies et al. 2010; Dunbar and Kurbatov 2011; Abbott and Davies 2012; Coulter et al. 2012). Until recently, analytical limitations of geochemical techniques have hindered adequate characterization of ultrafine glass particles (<5 µm) and identification of their eruptive source. Similarly, sulfate records in ice cores may not always act as suitable proxies for the occurrence of tephra or cryptotephra deposits composed of (typically sparse) glass shards in the cores (Davies et al. 2010; Abbott and Davies 2012).

Characterizing Tephra and Cryptotephra in the Laboratory

The characterization, or “fingerprinting,” of mineral and glass components of tephra or cryptotephra can be undertaken using a range of analytical methods (Table 1). Such characterization is almost always carried out in conjunction with lithostratigraphic and chronological criteria to obtain cogent correlations (Alloway et al. 2013).

Ferromagnesian Silicate Mineral Assemblages

A common method is to use a petrographic microscope to identify ferromagnesian or mafic mineralogical assemblages where such minerals are abundant, usually at proximal or medial sites. These minerals can be extracted using a magnetic separator together with nontoxic heavy liquids such as sodium polytungstate. With stratigraphic and age constraints, the relative abundances of ferromagnesian minerals may allow a source volcano to be identified. For example, in the Yukon Territory of Canada, Preece et al. (2000, 2011a) showed that tephra erupted from the Aleutian arc-Alaska Peninsula, so-called Type I beds, had low crystal contents comprising mainly pyroxene (and mainly bubble-wall shards), whereas tephra derived from the Wrangell volcanic field and Hayes volcano, Type II beds, generally had high crystal contents comprising mainly hornblende (and mostly pumiceous shards). In New Zealand, orthopyroxene (mainly hypersthene) is dominant in tephra erupted from the Taupo Volcanic Centre since c. 30,000 cal. year BP, whereas biotite,

Table 1 Analytical methods (excluding geochronology) used to characterize glass or minerals in tephra to facilitate their correlation (after Lowe 2011)

Tephra components and properties	Main methods of analysis ^a
Glass shards^b	
Major and minor elements ^c	Electron microprobe
Trace elements ^c including rare earths	LA- or SN-ICPMS, INAA, SIMS
Sr, Nd, and Pb isotopes	LA-ICPMS, multi-collector NMS
Shard morphology	Optical microscope, SEM
Melt inclusions (glass)	
Major and minor elements	Electron microprobe
Trace elements	SIMS, LA-ICPMS
Ferromagnesian silicate minerals	
Assemblages or marker minerals	Petrographic microscope, XRD
Pyroxenes, amphiboles, olivine, or biotite crystals/phenocrysts	Electron microprobe
Crystal geometry	Optical microscope, SEM
Apatite, zircon	
Apatite or zircon ^d crystals/phenocrysts	Electron microprobe, TIMS-TEA
Crystal geometry	Optical microscope, SEM
Fe-Ti oxides	
Major and minor elements	Electron microprobe
Eruption temperatures and oxygen fugacities	Electron microprobe
Feldspars^d	
Plagioclase, anorthoclase, or sanidine crystals/phenocrysts	Electron microprobe

^aLA- or SN-ICPMS laser ablation or solution nebulization inductively coupled plasma mass spectrometry, INAA instrumental neutron activation analysis, SIMS secondary ionization mass spectrometry (ion probe), NMS nuclide mass spectrometry, SEM scanning electron microscopy, XRD X-ray diffraction, TIMS-TEA thermal ionization mass spectrometry-trace element analysis

^bMay also include glass coats (selvedges) or matrix glass in pumice clasts

^cMajor elements expressed as oxides usually are defined as >1 wt%, minor element oxides as 0.1–1 wt%, and trace elements as <0.1 wt% or <1,000 parts per million (ppm) of the element (not oxides)

^dAnalyses of these minerals generally are less useful for correlating individual tephra

hornblende, cummingtonite, or orthopyroxene predominate in tephra erupted from the Okataina Volcanic Centre over the same period (Lowe et al. 2008).

In some cases an individual tephra can be identified using distinctive, diagnostic marker minerals, such as aegirine and aenigmatite in the Tuhua Tephra that were erupted from peralkaline Mayor Island volcano c. 7,000 cal. year BP in New Zealand. However, the absence of diagnostic minerals does not necessarily negate correlation because minerals such as olivine, biotite, and hypersthene can be dissolved comparatively quickly in some very acid peat bogs (within 700 years; Hodder et al. 1991) or in soil-forming environments (Lowe 1986; Churchman and Lowe 2012). Ferromagnesian minerals and Fe-Ti oxides also tend to be sparse or absent at distal localities, dropping out from proximal or medial ash clouds earlier because of their high density (Juvigné and Porter 1985).

Although of limited application, the crystal geometry (crystal width) of apatite (a phosphate-group mineral) was shown to be useful, along with apatite trace-element data, for differentiating beds in a study of Late Ordovician K-bentonites in the USA by Sell and Samson (2011). Similarly, Donoghue et al. (1991) showed that two distinct crystal geometries of olivine (skeletal, non-skeletal) were useful in correlating some andesitic tephra in New Zealand.

Major-Element Analysis of Glass Shards, Melt Inclusions, and Minerals

The electron microprobe enables a range of tephra components to be analyzed for major elements on a grain-by-grain basis: individual glass shards, glassy coatings on crystals, melt inclusions (glass preserved within crystals including quartz, pyroxenes, amphiboles), pumice fragments, and loose crystals or phenocrysts including various ferromagnesian silicate minerals, apatite, zircon, and Fe-Ti oxides such as titanomagnetite (Table 1). The main advantage of the microprobe and other single-grain techniques is that they allow mixed or heterogeneous populations to be identified. Because volcanic glass is amorphous, its analysis by microprobe needs especially careful sample preparation and mounting, the use of appropriate standards, and optimum probe-operating conditions to derive accurate and robust data (Kuehn et al. 2011; Hall and Hayward 2014; Pearce et al. 2014; Suzuki et al. 2014).

Usually a defocused (e.g., 10–20 μm) or rastered beam is deployed to minimize the mobilization of Na, although protocols that use narrower beam diameters (3–5 μm) without loss of Na have been recently developed for analyzing fine-grained glass shards, as occur in distal or ultra-distal tephtras or cryptotephtras or glasses with microlites (Hayward 2012; Pyne-O'Donnell et al. 2012; Hall and Hayward 2014). Glass microprobe analyses are usually normalized (summed to 100 %, most, but not all, of the deficit being attributable to water) to enable useful comparisons of analyses (Shane 2000; Lowe 2011; Westgate et al. 2013a). Using stratigraphic or age constraints, and usually also a knowledge of geochemical affinities of potential source rocks/deposits and spatial distribution patterns, the microprobe analysis of glass may allow tephra source volcanoes to be identified, and individual eruptives may also be correlated in some cases where compositions through time have changed from one eruptive event to the next. Complexities arise where glass analyses show heterogeneity, a consequence potentially of (i) mingling or mixing of separate batches of magmas that were tapped simultaneously or sequentially as eruptions proceeded (e.g., Tryon et al. 2010; Turner et al. 2011b), (ii) major-element evolution by fractional crystallization or crustal assimilation (Bogaard and Schminke 1985; Ukstins Peate et al. 2008; Óladóttir et al. 2012), (iii) blending of thin tephtras in soil-forming or cryogenic environments (Lowe 1986; Eden et al. 2001; Dugmore and Newton 2012), or (iv) postdepositional dissemination of glass shards in peat, lake, or marine sediments (Gehrels et al. 2006; Allan et al. 2008; Abbott et al. 2013). Heterogeneity arising from magmatic or volcanic eruption processes accompanied by changes in wind direction warns of the difficulty of characterizing (thus fingerprinting) tephra beds using a limited set of distal samples from restricted dispersal sectors (Shane et al. 2008a). Another problem can arise with analyses of melt inclusions where these do not reflect the full compositional range of glass shards or matrix glass (e.g., Shane et al. 2008b; Chesner and Luhr 2010; Allan et al. 2013), or they show a pattern different from that associated with matrix glass analyses (e.g., Kilgour et al. 2013). Once recognized, such compositional variability can enhance correlation by providing additional fingerprinting criteria, but sampling from the full spatial and temporal range of deposits of an eruptive sequence is required (Alloway et al. 2013).

The correlation of andesitic or basaltic tephtras using glass chemistry generally can be complicated for various reasons including the multiplicity of units, the paucity of suitable glass for microprobing (shards may contain micro-inclusions and can be highly vesicular), susceptibility of glass to weathering, and wide compositional ranges and potential heterogeneity as noted previously (Moebis et al. 2011; Shane and Zawalna-Geer 2011; Óladóttir et al. 2012). Platz et al. (2007) provided a procedure to evaluate glass compositional variability arising from the inadvertent microanalysis of plagioclase microlites in shards using a wide beam, but the recent use of narrower beam diameters is helping to obviate this problem (Hayward 2012; Pearce et al. 2014).

Analyses by microprobe of ferromagnesian silicate minerals, such as biotite (Shane et al. 2003; Smith et al. 2011) and cummingtonite (Matsu'ura et al. 2012), apatite (a phosphate-group mineral) (Sell and Samson 2011), and Fe-Ti oxides such as titanomagnetite and ilmenite (Shane 1998; Preece et al. 2011b; Marcaida et al. 2014), have also been used for tephra fingerprinting. In some cases, and after taking into account compositional zoning within crystals, trace elements such as Mg, Cl, Mn, Fe, Ce, and Y identified in apatite crystals and phenocrysts provide a means of distinguishing or matching tephras (Sell and Samson 2011). The eruption temperature and oxygen fugacity (oxidation state of magma) of rhyolitic tephras – estimated using single-grain EMPA of Fe-Ti oxide pairs of titanomagnetite and ilmenite – provide another way to correlate tephras and, in some cases, magma batches within an eruptive sequence (Smith et al. 2005; Preece et al. 2011b; Marcaida et al. 2014).

Trace-Element and Isotope Analysis of Glass

Although the microprobe is now the key analytical tool for undertaking major-element analyses of glass, tephras or cryptotephras cannot always be distinguishable uniquely by major-element data alone. In these cases, other analytical methods are needed (Westgate et al. 2013c). Trace-element analyses of glass separates from tephra or cryptotephra deposits offer a greater range of elements for use in correlation/provenance studies and may also provide additional information on volcanic petrogenesis. In the last decade, trace-element techniques have become more common, the most widely available being laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS) (e.g., Albert et al. 2012; Ponomareva et al. 2013a; Sulpizio et al. 2013) (Table 1). Around 150 individual glass shards can be analyzed for about 30 trace elements in 1 day using LA-ICPMS (Pearce et al. 2011). Comprehensive studies using this method were undertaken on Pleistocene tephras in northern New Zealand (Pearce et al. 2008b) and in marine cores from Ocean Drilling Project (ODP) Site 1123 (Allan et al. 2008). The most useful elements for correlating and distinguishing between the ODP Site 1123 tephras were found to be the abundances of Rb, Ba, Sr, Y, Zr, Hf, Mg, Mn, and Ti and trace-element ratios including Rb/Sr, Ba/Sr, Zr/Y, Y/Th, Ba/Th, and Rb/Sm. Using trace-element data for glass shards, Allan et al. (2008) demonstrated that (i) tephras with similar major-element compositions (e.g., Kawakawa tephra vs. Omataroa tephra) were easily distinguishable (Fig. 7), and (ii) two previously unidentified repeated sections of ODP cores 1123A (~4.5 m thick) and 1123C (~7.9 m thick) were recognized (Allan et al. 2008). As with the microprobe, there is a possibility of microlites affecting trace-element characterizations of individual shards via LA-ICPMS and so anomalous assays need to be evaluated carefully (Abbott et al. 2013).

Analyses of isotopes of Sr, Nd, and Pb in glass (or pumices) have been utilized in several studies to help determine tephra source volcanoes (e.g., Roulleau et al. 2009; Westgate et al. 2008, 2011; Giaccio et al. 2013).

Comparing Compositional Data Using Graphical, Numerical, and Statistical Methods

Major- or trace-element datasets obtained from analyses of glass or minerals may be displayed and compared, and hence compositional variability evaluated, using various methods: graphical (e.g., bivariate or trivariate plots), numerical (e.g., similarity coefficients), or statistical (e.g., statistical distance measure, dendrograms, discriminant function analysis, principal components analysis) (Pearce et al. 2008a; Bourne et al. 2010; Lowe 2011; Sell and Samson 2011). In many cases, the bivariate plots alone can provide sufficient guidance to enable anomalous data points to be identified (and possibly explained using compositional databases for comparison), and potential correlations or otherwise established with reasonable likelihood, especially where multiple criteria provide

Fig. 7 Bivariate plots for some major and trace elements derived from analyses of individual glass shards from two New Zealand tephra, Omataroa (c. 31,600 cal. year BP, erupted from Okataina Volcanic Centre) and Kawakawa (c. 25,400 cal. year BP, erupted from Taupo Volcanic Centre), identified in marine cores *A*, *B*, and *C* from ODP Site 1123 about 1,200 km east of New Zealand (Modified after Allan et al. 2008, p. 2351, with permission of Elsevier). (a) CaO versus FeO_t (total iron expressed as FeO) derived by electron microprobe. Glass analyses from an onshore occurrence of Kawakawa tephra (at Irirangi) are also shown for comparison. The plot shows that the analyses of marine and onshore samples of Kawakawa tephra are identical and that Kawakawa and Omataroa tephra cannot be distinguished using these two oxides alone. In contrast, trace-element concentrations (in ppm), derived by LA-ICPMS, in (b) and (c), show that the tephra are distinctly different with respect to their elements/element ratios and hence can be readily distinguished

independent support, such as concordance of glass major- and trace-element data together with Fe-Ti oxide data (e.g., see Preece et al. 1999, 2011b). In other situations, however, statistical methods such as principal components analysis can allow units to be distinguished objectively on the basis of multiple oxides or elements (not just two or three) analyzed from glass shards or crystals (e.g., Tryon et al. 2010; Chiasera and Cortés 2011; Sell and Samson 2011).

Dating Tephra (Tephrochronometry)

Tephra may be dated directly using primary minerals (e.g., zircon, hornblende, K-feldspars, biotite, quartz) or glass from within the tephra layer, or indirectly on either enclosing or encapsulated material, using a range of methods including radiometric, incremental (e.g., varves, layering in ice), and age equivalence (Table 2) (Svensson et al. 2008; Alloway et al. 2013; Zalasiewicz et al. 2013). These ages can then be transferred from one site to another where the tephra is recognized using the lithostratigraphic and compositional-based methods described above. Only the main radiometric methods, and age modeling, are touched on here.

Table 2 Methods used for dating tephtras directly or indirectly (after Lowe 2011)

Main method	Applications
Radiometric	Radiocarbon dating (radiometric/beta counting, AMS) ^a Fission-track dating of zircon or glass-ITPFT or glass-DCFT dating Argon isotopes (K/Ar, Ar/Ar including SCLP/F, LIH) Luminescence dating (TL, OSL, IRSL, pIR-IRSL) U-series including (U-Th)/He, U-Pb, and ²³⁸ U/ ²³⁰ Th zircon dating (SIMS/TIMS, SHRIMP, LA-ICPMS) Electron spin resonance ²¹⁰ Pb, ¹³⁷ Cs, ³ He and ²¹ Ne surface exposure dating
Incremental	Dendrochronology, varve chronology, layering in ice cores (ice sheets/caps, glaciers)
Age equivalence	Magnetopolarity, paleomagnetic secular variation, astronomical (orbital) tuning, correlation with marine oxygen isotope stages, climatostratigraphy, biostratigraphy, palynostratigraphy, paleopedology
Age modeling	Various age-depth methods including Bayesian flexible depositional modeling and wiggle matching, spline-fit modeling
Relative	Obsidian hydration dating, amino acid racemization
Historical	Eyewitness accounts or observations (e.g., via remote sensing)

^aAMS accelerator mass spectrometry, ITPFT isothermal-plateau fission track, DCFT diameter-corrected fission track, SCLP/F single-crystal laser probe or fusion, LIH laser incremental heating, TL thermoluminescence, OSL optically stimulated luminescence, IRSL infrared stimulated luminescence, pIR-IRSL post infrared-infrared stimulated luminescence, SIMS secondary ionization mass spectrometry, TIMS thermal ionization mass spectrometry, SHRIMP sensitive high-resolution ion microprobe, LA-ICPMS laser ablation inductively coupled plasma mass spectrometry

For tephtras erupted within the past c. 60,000 calendar years, the radiocarbon (¹⁴C) technique (e.g., Hogg et al. 2007) remains the most important method for developing calibrated age models. In recent years, the advantages of using pollen concentrates and terrestrial plant macrofossils (e.g., leaves, twigs), rather than bulk organic samples, as reliable dating materials via AMS have been demonstrated (Newnham et al. 2007; Staff et al. 2011). Together with dendrochronological wiggle-matching methods (Hogg et al. 2012; Yin et al. 2012), Bayesian flexible depositional age modeling has added a revolutionary aspect to the construction of enhanced and more precise chronologies in tephrochronology involving ¹⁴C and other dating methods (Blockley et al. 2008; Smith et al. 2013). Lowe et al. (2013) dated late Quaternary tephtras in New Zealand by modeling ¹⁴C age data using two Bayesian-based programs, *Bacon* (Blaauw and Christen 2011) and OxCal's *P_Sequence* function (Bronk Ramsey 2009), and the IntCal09 dataset (Fig. 8). Lohne et al. (2013) also used *P_Sequence* and IntCal09 to obtain high-precision ages of 12,066 ± 42 and 10,210 ± 35 cal. year BP (±1σ) for the Vedde and Saksunarvatn tephtras, respectively, from sediments in Kråkenes Lake, Norway. Similarly, the AT tephtra of Japan was dated to 30,009 ± 189 cal. year BP (95 % probability) using *P_Sequence* modeling of ¹⁴C data and varves (Smith et al. 2013). Vandergoes et al. (2013) used OxCal's *Tau_Boundary* function, also Bayesian, to precisely date the Kawakawa/Oruanui tephtra of New Zealand to 25,358 ± 162 cal. year BP (95 % probability).

Another key advance in tephrochronology has been the development of the isothermal-plateau fission-track dating method (ITPFT) for glass (Westgate 1989; Alloway et al. 2004b, 2013; Westgate et al. 2013b). ITPFT and the diameter-corrected fission-track method (Sandhu and Westgate 1995) have enabled ages to be obtained on many distal vitric-rich tephtras that previously were unable to be dated because of low abundance of dateable mineral constituents, fine grain size, and the presence of detrital grains. Examples of such applications include dating Quaternary glacioeustatic sedimentary cycles in the Wanganui Basin (Alloway et al. 1993; Pillans et al. 2005) and dating initial loess deposition in Alaska at ~3 million years ago (Westgate et al. 1990). The glass-FT techniques have

Fig. 8 Bayesian-derived age models (95 % probability) for nine late Quaternary tephras in New Zealand (From Lowe et al. 2013, p. 179, with permission of Elsevier). Probability plots are colored according to tephra source volcanoes: *red*, Okataina; *orange*, Taupo; *green*, Taranaki; and *blue*, Tongariro. *Gray* plots show the start and end ages of the lateglacial cool episode, designated climate event NZce-3 by Barrell et al. (2013), in part constrained chronologically by the ages on the adjacent tephras

been used, for example, also to test chronologies based on alternative methods (such as magnetic polarity and astronomical tuning) for marine tephra sequences (Alloway et al. 2005; Allan et al. 2008) and for fossiliferous alluvial and lacustrine sediments in Beringia (Preece et al. 2011b; Westgate et al. 2013a).

Where suitable minerals are available (e.g., sanidine, biotite, leucite, anorthoclase), the $^{40}\text{Ar}/^{39}\text{Ar}$ method has been useful, such as dating the Laacher See tephra in Germany (Bogaard 1995), the ultra-distal to distal deposits of the Youngest Toba Tuff tephra of Indonesia (Westgate et al. 1998; Storey et al. 2012), a widespread Holocene tephra erupted from Ulleungdo stratovolcano in South Korea (Smith et al. 2013), a 400,000-year-old sequence of eruptives from Nemrut volcano preserved in Lake Van, eastern Anatolia in Turkey (Sumita and Schminke 2013), and the distal tephras preserved in lacustrine and fluvial sediments of intermontane basins of central Italy (Giaccio et al. 2013). A relatively new method for dating proximal pyroclastic deposits, previously applied to petrologic studies, is the use of U-Pb analyses to date zircons (Schmitt 2006; Dickinson et al. 2010; Wilson et al. 2010). Luminescence and (U-Th)/He dating methods are also being applied systematically to tephras (Danišík et al. 2012; Biswas et al. 2013).

A trend in dating lake sediment sequences containing tephras or cryptotephra is to apply multiple methods, as exemplified by Staff et al. (2013) and Sirocko et al. (2013).

Conclusions

Tephrochronology is the use of primary tephra or cryptotephra as isochrons to link and synchronize geological, paleoenvironmental, or archaeological sequences or events, or soils, and, uniquely, to transfer relative or numerical ages to them using stratigraphic information and mineralogical and geochemical compositional data, especially from individual glass-shard analyses, obtained for the

tephras/cryptotephras. To function therefore as an age-equivalent correlation and chronostratigraphic dating tool, tephrochronology can be undertaken in three steps: (i) mapping and describing tephras and determining their stratigraphic relationships, (ii) characterizing tephras or cryptotephras in the laboratory, and (iii) dating them using a wide range of geochronological methods. Tephrochronology is also an important tool in volcanology, informing studies on volcanic petrology, volcano eruption histories and hazards, and volcano-climate forcing. Although limitations and problems remain, multidisciplinary applications of tephrochronology continue to grow markedly (e.g., Alloway et al. 2013; Lane et al. 2014).

Acknowledgments

We thank editors Jeroen Thompson and Jack Rink for inviting us to write this entry and for their suggestions, reviewer Vera Ponomareva for her helpful comments, Megan Balks and Adam Brumm for providing photographs, and Chris Hayward and John Westgate for furnishing preprints. Elsevier kindly allowed us to use previously published material (Figs. 7 and 8). The entry was funded in part by the New Zealand Marsden Fund (project 10-UOW-056 to DJL entitled “New views from old soils”), administered by the Royal Society of New Zealand, and it is an output also of the INTREPID Tephra-II project (INQUA project 1307s) “Enhancing tephrochronology as a global research tool through improved fingerprinting and correlation techniques and uncertainty modelling (phase II),” an initiative of the International Focus Group on Tephrochronology and Volcanism (INTAV) supported by the Stratigraphy and Chronology Commission of the International Union for Quaternary Research (INQUA).

Synonyms

[Chronostratigraphy](#); [Stratigraphic correlation using tephra](#); [Tephrostratigraphy](#)

Definitions

Tephra. All the explosively erupted, unconsolidated pyroclastic products of a volcanic eruption.

Cryptotephra. Tephra-derived glass-shard and/or crystal concentration preserved in sediments or soils/paleosols but not visible as a layer to the naked eye.

Tephrostratigraphy. Study of sequences of tephra layers or cryptotephra (and associated deposits) and their lithologies, spatial distribution, stratigraphic relationships, and relative and numerical ages. Involves defining, describing, characterizing, and dating tephra layers or cryptotephra deposits in the field and laboratory as a basis for their correlation.

Tephrochronometry. Obtaining a numerical age or calendrical date for a tephra or cryptotephra deposit.

Tephrochronology sensu stricto. The use of primary tephra layers or cryptotephra as isochrons to connect and synchronize depositional sequences, or soils, and to transfer relative or numerical ages to the sequences or soils using lithostratigraphic, compositional, and other data pertaining to the tephra/cryptotephra.

Tephrochronology sensu lato. All aspects of tephra/cryptotephra studies and their application.

Introduction and Definitions

Tephra are the explosively erupted, unconsolidated pyroclastic (fragmental) products of a volcanic eruption (Greek *tephra*, “ashes”) (Lowe 2011). Typically they comprise volcanic glass (including shards, pumice, and scoriae or cinders), rock (lithic) fragments, and crystals (mineral grains), which are erupted through the atmosphere and deposited on the land, the seafloor, or ice caps relatively quickly – usually in a matter of hours or days according to eruption duration (Lowe 2011; Stevenson et al. 2012). A tephra layer deposited from a powerful eruption, and not reworked, consequently forms a widespread, thin blanket on the surface of the Earth that has effectively the same age – an isochron – wherever it occurs. The term “tephra” encompasses all grain sizes: ash (grains <2 mm in diameter), lapilli (64 to 2 mm), or blocks (angular) or bombs (rounded) (>64 mm) (White and Houghton 2006). Diminutive, distal tephra that are not visible as layers in the field are called cryptotephra (Greek *kryptein*, “to hide”). Cryptotephra comprise concentrations of ash-sized glass

*Email: d.lowe@waikato.ac.nz

shards or crystals, or both, usually $<150\text{ }\mu\text{m}$ in diameter, preserved in sediments (including ice), in cave deposits, or in soils or paleosols (Lowe 2011; Lane et al. 2014).

Tephrochronology may be defined as the use of primary tephra layers or cryptotephra deposits as isochronous beds to connect and synchronize depositional sequences and to transfer relative or numerical ages (or dates) to such sequences using stratigraphic information together with lithological, compositional, and geochronological data obtained for the tephra or cryptotephra. Tephrochronology is thus a method for correlating and dating geological, paleoecological, paleoclimatic, or archaeological sequences or events, or soils, using characterized tephra or cryptotephra as chronostratigraphic marker beds (Alloway et al. 2013).

Tephrochronology is undertaken typically in three steps. Firstly, tephra deposits are correlated from place to place in the field using their lithostratigraphic and relative age relationships along with intrinsic physical properties, associations with other deposits, and spatial distribution, i.e., tephrostratigraphy (Fig. 1). Fieldwork is carried out at a range of scales because tephra deposits become thinner, and constituent components become smaller, from proximal to distal locations. A potential complication is tephra remobilization, which is discussed later. Secondly, the components of the deposits are characterized or “fingerprinted” using mineralogical or geochemical analytical methods, often both, in the laboratory to aid their correlation. Such laboratory characterization is essential in cryptotephra studies. Thirdly, when a numerical age or date for a tephra or cryptotephra deposit is obtained, i.e., tephrochronometry, that age or date can be transferred from

Fig. 1 Stratigraphic sequence of four Holocene tephra deposits of ash and lapilli grade, and buried soil horizons, near Mt Tarawera, New Zealand. Exposure is $\sim 2\text{ m}$ high. From *top*, Tarawera tephra (mainly Rotomahana Mud member) (erupted 10 June 1886); shower-bedded Kaharoa tephra ($\text{AD } 1314 \pm 12$), characterized by abundant biotite; Taupo tephra ($\text{AD } 232 \pm 10$) (note that the *gray* and *very dark-brown* soil horizons evident in the *upper part* of the nonwelded Taupo deposit, Taupo ignimbrite, are the result of podzolization, an acidic soil-leaching process that occurred here prior to the soil's burial by the Kaharoa eruptives); and Whakatane tephra ($5,526 \pm 145\text{ cal. year BP}$) (Ages from Lowe et al. 2013) (Photo: Megan Balks)

one site to the next by comparing the compositional characteristics or “fingerprints” of its components with those of equivalent deposits elsewhere. These three steps – (i) mapping tephras and determining their lithostratigraphic relationships, (ii) characterizing tephras/cryptotephras in the laboratory, and (iii) dating them – enable tephrochronology to function as a unique stratigraphic and geoscientific dating tool and are described below in detail after a subsection on volcanological applications.

Volcanological Applications of Tephrochronology

As well as providing isochrons for geological, archaeological, and paleoenvironmental applications, tephrochronological studies involving mapping, characterization, and dating are critical for developing a comprehensive record of past explosive eruptions and recurrence rates from which time-space relationships of volcanism can be established and volcanic hazards evaluated (e.g., Óladóttir et al. 2008; Kuehn and Negrini 2010). Knowledge of the distribution and thickness relationships of tephra or cryptotephra deposits enables magma volumes to be calculated (Wilson et al. 2009; Ponomareva et al. 2013a). Near to volcanic centers, deposits may include lavas as well as an array of different types of pyroclastic deposits (fall, surge, flow and density current, and explosion breccias; Fig. 2), and detailed studies of their stratigraphic intercalation and physical, mineralogical, and geochemical properties provide insight into volcanic history and petrogenesis (e.g., Ponomareva et al. 2004; Smith et al. 2005; Turner et al. 2011a; Cioni et al. 2014). Information about the release of volatiles into the atmosphere and associated climatic impacts can also be gleaned from studies on tephras (e.g., Zdanowicz et al. 1999; Alloway et al. 2013; Sigl et al. 2013).

Mapping and Correlating Tephras

The most successful approaches in the field include the so-called hand-over-hand method whereby relatively thick sequences of tephras, typically meter to decimeter scale, at proximal or medial locations, are documented and traced from one outcrop or section to the next using distinctive physical properties in combination with their stratigraphic associations (Fig. 3). Physical properties include color, bedding characteristics, or particle-specific features such as pumice/scoria, lithic, and crystal componentry, the presence of accretionary lapilli, or marker mineral grains (crystals) such as biotite identifiable via a hand lens. Distinctive marker beds provide a useful stratigraphic starting point in unraveling the complexities of geological sequences seen in road cuttings or natural exposures, and detailed lithostratigraphic columns are constructed to provide the basis essential for correlating from one site to the next (Fig. 3). The nature of buried soil horizons, loess, or other deposits associated with tephra layers, including (for example) fossils or other attendant paleoecological information such as pollen assemblages (e.g., Newnham and Lowe 1999; Housley et al. 2013; Westgate et al. 2013a) or archaeological relationships (Feibel 1999; Mullen 2012; Riede and Thastrup 2013), may provide additional contextual information helpful for affecting correlation (Fig. 4). High-resolution tephrostratigraphic records in Iceland were constructed by Streeter and Dugmore (2013) using digital photography to obtain thousands of stratigraphic measurements of multiple tephra layers intercalated with sediments at a resolution of 1 mm.

One potential difficulty in tephrostratigraphy arises where tephra remobilization has occurred or where glass shards or crystals have been disseminated or dispersed in sediments or soils, and hence, primary isochron positions are not clear (Alloway et al. 2004a; Pyne-O'Donnell 2011; Housley et al. 2012). Remobilization of tephra resulting from widespread landscape instability in combination with climatic factors (e.g., Manville and Wilson 2004) can remobilize large volumes of tephra

Fig. 2 (a) Road section in the vicinity of Lago Blanco, Chaitén sector (42°S), southern Chile. The stratigraphy at this section reveals (from *top*) a prominent rhyolitic (c. 76 % SiO₂) pumiceous lapilli deposit (Cha-1 correlative) dated at c. 8,700 ¹⁴C year BP and sourced from an ancestral Chaitén volcano, closely overlying a rhyolitic (c. 71 % SiO₂) surge and fall couplet informally named Lepué tephra. This lower rhyolitic eruptive couplet, dated at c. 9,800 ¹⁴C year BP, is sourced from the nearby Michinmahuida Volcanic Complex (MVC). The buried soil horizon (“andic paleosol”) marks the hiatus between the Lepué and Cha-1 eruptions. (b) Low-angle cross-bedding and crosscutting relationship of the surge deposit across its co-eruptive fall deposit, Lepué tephra. (c) The Michinmahuida-sourced eruptive couplet is closely underlain by a widespread and distinctive layer of banded high-Si rhyolite breccia (indicated by *arrows*) that likely represents the products of an explosion of a pre-Cha-1 lava dome (ancestral Chaitén volcano). Such sections are particularly important in terms of recognizing eruptives with different field expression and composition, as well as for unraveling the complex and variable histories of closely situated (adjacent) eruptive centers (Photos: Brent Alloway)

for decades in the aftermath of a paroxysmal eruption (e.g., following the 1991 Pinatubo eruption; Torres et al. 2004). Remobilization of tephra can also be triggered by human activities (Swindles et al. 2013). Such reworked or disseminated tephra-derived constituents, including glass shards, form diachronous rather than isochronous surfaces, and hence, their use as stratigraphic tie points is compromised unless remobilization is very localized or near contemporaneous with the primary depositional event. The non-reworked part of a tephra deposit provides an isochron of maximum age (the date of the tephra eruption and primary deposition), but any reworked components are younger (Lowe 2011).

Field correlation methods are increasingly limited as the tephra layers become thinner and finer with increasing distance away from source (e.g., Fig. 5), and the tephtras may become more irregularly distributed (e.g., Turney and Lowe 2001; Lawson et al. 2012). The tephtras typically lose diagnostic physical features (such as internal bedding) in subaerial sequences, and thin, separate beds can become mixed together by soil-forming processes including bioturbation or by cryoturbation in periodically or perennially frozen landscapes (Sanborne et al. 2006; Lowe and

Fig. 3 Stratigraphic columns and corresponding section photos detailing the tephrostratigraphy of deposits at two sites, Santa Barbara and Puerto Cardenas, in the Chaitén sector (42°S) of southern Chile. The tephra notation is from Naranjo and Stern (2004). A key tephra of interest is the prominent decimeter-thick gray tephra layer (Cor-1; now more recently and informally referred to as Lepué tephra) that contains conspicuous accretionary lapilli throughout. This tephra is the product of a large-scale phreatomagmatic eruption sourced from the glaciated Michinmahuida Volcanic Complex (MVC) dated at c. 9,800 ^{14}C year BP. Tephra from the 2008 eruption of Chaitén volcano occurs on the present-day ground surface. Other strongly pedogenically weathered tephra beds represented within these sections have yet to be geochemically characterized and are probably variably sourced from other nearby volcanoes (Puyuhuapi, Melimoyu, Yanteles, and Corcovado). The tephra sequences at both localities rest on glacial till with a minimum age of c. 14,000 ^{14}C year BP (Photos: Brent Alloway)

Tonkin 2010; Dugmore and Newton 2012). Cores taken from lake sediments and peat bogs potentially provide a reliable means to record thin and/or fine-grained distal tephra layers, or at proximal or medial locations where tephra tend to be thicker and may have more restricted dispersal patterns around source vents – for example, in basaltic volcanic fields (Shane and Hoverd 2002). These lake or bog depositional environments allow thin tephra or glass-shard concentrations (cryptotephra) to be preserved amidst organic-bearing sediments (Fig. 6) (de Fontaine et al. 2007; Smith et al. 2013), notwithstanding potential taphonomic difficulties posed by tephra reworking or dispersion (Lowe 2011; Liu et al. 2014). Marine cores, especially from locations downwind of eruption centers, may also contain detailed records of tephra layers or cryptotephra intercalated with sediments (e.g., Guðmundsdóttir et al. 2012; Abbott et al. 2013; Ponomareva et al. 2013b; Austin et al. 2014). Possible reworking of tephra (by currents, ice rafting, bioturbation) adds complexity in some cases (Brendryen et al. 2010; Larsen et al. 2014; Todd et al. 2014).

Together with those from lakes and bogs, many of the records of marine tephra deposits can thus document patterns of explosive volcanism in time and space and integrate the stratigraphic interfingering of eruptives from multiple volcanic sources (Shane et al. 2006; Swindles et al. 2011; Ponomareva et al. 2013a, b). Such compilations are often more comprehensive than those obtainable near volcanic centers because of burial or erosion of eruptives at such proximal locations, but an important caveat is that proximal deposits are typically more compositionally variable than distal deposits (e.g., Smith et al. 2005; Shane et al. 2008a). On this basis, distal deposits usually have a more restricted compositional range than otherwise might be generated during a particular eruptive episode.

Fig. 4 Stratigraphy associated with hominin stone artifacts and vertebrate fossil remains from the So'a Basin, central Flores, Indonesia (unpublished data of B. V. Alloway, A. Brumm, G. van den Bergh, and R. Setiawan; after O'Sullivan et al. (2001) and Brumm et al. (2010)). The in situ stone artifacts occur immediately beneath a nonwelded (unconsolidated) ignimbrite deposit (Wolo Sege ignimbrite, WSI) that can readily be correlated and distinguished from other enveloping silicic tephra interbeds across the So'a Basin on the basis of its unique depositional architecture as well as its major-element glass-shard composition. The WSI, dated at 1.02 ± 0.02 Ma by $^{40}\text{Ar}/^{39}\text{Ar}$ (Brumm et al. 2010), provides important evidence for the presence of hominins on Flores for over 1 million years. (a) The base of WSI at the Wolo Sege section showing distinctive surge-like subunits containing accretionary lapilli and bedding consistent with the density segregation of entrained particles. Note the in situ bifacial flake in the paleosol immediately beneath the base of the WSI (indicated by arrow). (b) Close-up photo of the in situ bifacial flake identified at Wolo Sege. (c) In situ flaked core stone identified at the Matago section on the paleo-ground surface buried by the WSI. (d) Close-up photo showing the detail of the flaked core stone from the Matago section (Photos a–c, Brent Alloway; Photo d, Adam Brumm)

Distal Tephra and Cryptotephra Deposits

Submillimeter-scale studies have involved the development of new approaches to enable cryptotephra, and very thin distal tephra, to be mapped, albeit discontinuously, across landscapes using a range of methods firstly to *detect* and *isolate* glass-shard or crystal concentrations (e.g., Hall and Pilcher 2002; Gehrels et al. 2006; Swindles et al. 2010; Lane et al. 2014) and secondly to *correlate* them with known (previously characterized) deposits using geochemical analyses of glass shards, melt inclusions (glass) within crystals, or crystals (Matsu'ura et al. 2011; Swindles et al. 2013) as described below. Cryptotephra have been discovered in peat, lake, marine, aeolian, or frozen sediments or ice, in deposits in caves or rock shelters, and in soils or paleosols. They (and thin visible tephra) have been detected using ground-penetrating radar, magnetic susceptibility and remanent magnetization, X-radiography, X-ray fluorescence (including use of scanners), spectrophotometry, micro-petrography, enumeration of glass shards, and measurements of total organic carbon and loss on ignition (Turney and Lowe 2001; Gehrels et al. 2008; Lawson et al. 2012). These

Fig. 5 A distal occurrence of fine-grained Mazama tephra, 1–2 cm in thickness and composed mainly of glass shards, shows up as the pale “break” (where the person is touching) in an alluvium-soil sequence on the lowermost terrace alongside the North Saskatchewan River in Edmonton, Alberta, Canada. Multiple buried soils formed on intermittent flood deposits are evident in the section, with the high sedimentation (up-building) rate contributing to the rapid burial and preservation of the thin, fine-grained Mazama tephra as an inconspicuous layer. The Mazama tephra, dated at $7,627 \pm 150$ cal. year BP (Zdanowicz et al. 1999), provides a key isochronous time plane (chronostratigraphic marker bed) for Holocene archaeological and paleoenvironmental studies in the USA and southwestern Canada. Located ~1,450 km northeast of its source (Crater Lake, Oregon), the tephra was first identified here by Westgate et al. (1969) (Photo: Maria Lowe)

novel cryptotephra studies, although not without problems and limitations (e.g., Davies et al. 2007; Payne and Gehrels 2010; Swindles et al. 2011), have documented tephra-fall occurrences at submillimeter scales at distances of hundreds to some thousands of kilometers from source, greatly extending known geographical limits (e.g., Payne et al. 2008; Davies et al. 2010, 2012; Balascio et al. 2011; Cullen et al. 2014). Pyne-O'Donnell et al. (2012) showed that “ultra-distal” cryptotephtras derived from Holocene eruptions in Alaska and the Pacific Northwest occur up to ~7,000 km from source in easternmost North America and one tephra, the Alaskan White River Ash (eastern lobe, erupted around AD 860), occurs over ~7,000 km away in Ireland (Jensen et al. 2014). Lane et al. (2013) identified the c. 75,000-year-old Youngest Toba Tuff tephra as a cryptotephra deposit in Lake Malawi sediments in east Africa, >7,000 km west of the source volcano in Sumatra. Cryptotephra associated with the eruption of the Campanian Ignimbrite in Italy c. 40,000 calendar (cal.) year BP was identified across much of central Europe and the Mediterranean area by Lowe et al. (2012). As noted earlier with regard to visible tephra deposits, cryptotephra studies can help also in elucidating the eruptive history of volcanoes (e.g., Shane et al. 2013).

Ice cores provide detailed and valuable records of volcanism (Davies et al. 2010; Dunbar and Kurbatov 2011; Abbott and Davies 2012; Coulter et al. 2012). Until recently, analytical limitations of geochemical techniques have hindered adequate characterization of ultrafine glass particles (<5 μm) and identification of their eruptive source. Similarly, sulfate records in ice cores may not

Fig. 6 Close-up of a near-basal part of a lake sediment core from Lake Okoroire, New Zealand, showing (in middle of photo) 3-cm-thick Rerewhakaaitu tephra, erupted $17,496 \pm 462$ cal. year BP from Mt Tarawera in the Okataina Volcanic Centre (Lowe et al. 2013; see Fig. 8 below). Many tiny *black specks* in the pale layer represent free biotite crystals diagnostic of this (and some other) tephras derived from Mt Tarawera. Different sediment colors above and below the tephra reflect a climatically driven change from shrubland/grassland to forest in the region soon after the eruption (Newnham et al. 2003; Alloway et al. 2007). An indistinct uncorrelated tephra lies ~2 cm above the Rerewhakaaitu tephra. Scale marks in centimeters (Photo: David Lowe)

always act as suitable proxies for the occurrence of tephra or cryptotephra deposits composed of (typically sparse) glass shards in the cores (Davies et al. 2010; Abbott and Davies 2012).

Characterizing Tephras and Cryptotephras in the Laboratory

The characterization, or “fingerprinting,” of mineral and glass components of tephras or cryptotephras can be undertaken using a range of analytical methods (Table 1). Such characterization is almost always carried out in conjunction with lithostratigraphic and chronological criteria to obtain cogent correlations (Alloway et al. 2013).

Ferromagnesian Silicate Mineral Assemblages

A common method is to use a petrographic microscope to identify ferromagnesian or mafic mineralogical assemblages where such minerals are abundant, usually at proximal or medial sites. These minerals can be extracted using a magnetic separator together with nontoxic heavy liquids such as sodium polytungstate. With stratigraphic and age constraints, the relative abundances of ferromagnesian minerals may allow a source volcano to be identified. For example, in the Yukon Territory of Canada, Preece et al. (2000, 2011a) showed that tephras erupted from the Aleutian arc-Alaska Peninsula, so-called Type I beds, had low crystal contents comprising mainly pyroxene (and mainly bubble-wall shards), whereas tephras derived from the Wrangell volcanic field and

Table 1 Analytical methods (excluding geochronology) used to characterize glass or minerals in tephra to facilitate their correlation (After Lowe 2011)

Tephra components and properties	Main methods of analysis ^a
Glass shards^b	
Major and minor elements ^c	Electron microprobe
Trace elements ^c including rare earths	LA- or SN-ICP-MS, INAA, SIMS
Sr, Nd, and Pb isotopes	LA-ICP-MS, multi-collector NMS
Shard morphology	Optical microscope, SEM
Melt inclusions (glass)	
Major and minor elements	Electron microprobe
Trace elements	SIMS, LA-ICP-MS
Ferromagnesian silicate minerals	
Assemblages or marker minerals	Petrographic microscope, XRD
Pyroxenes, amphiboles, olivine, or biotite crystals/phenocrysts	Electron microprobe
Crystal geometry	Optical microscope, SEM
Apatite, zircon	
Apatite or zircon ^d crystals/phenocrysts	Electron microprobe, TIMS-TEA
Crystal geometry	Optical microscope, SEM
Fe-Ti oxides	
Major and minor elements	Electron microprobe
Eruption temperatures and oxygen fugacities	Electron microprobe
Feldspars^d	
Plagioclase, anorthoclase, or sanidine crystals/phenocrysts	Electron microprobe

^aLA- or SN-ICP-MS laser ablation or solution nebulization inductively coupled plasma mass spectrometry, INAA instrumental neutron activation analysis, SIMS secondary ionization mass spectrometry (ion probe), NMS nuclide mass spectrometry, SEM scanning electron microscopy, XRD X-ray diffraction, TIMS-TEA thermal ionization mass spectrometry-trace element analysis

^bMay also include glass coats (selvedges) or matrix glass in pumice clasts

^cMajor elements expressed as oxides usually are defined as >1 wt%, minor element oxides as 0.1–1 wt%, and trace elements as <0.1 wt% or <1,000 parts per million (ppm) of the element (not oxides)

^dAnalyses of these minerals generally are less useful for correlating individual tephra

Hayes volcano, Type II beds, generally had high crystal contents comprising mainly hornblende (and mostly pumiceous shards). In New Zealand, orthopyroxene (mainly hypersthene) is dominant in tephra erupted from the Taupo Volcanic Centre since c. 30,000 cal. year BP, whereas biotite, hornblende, cummingtonite, or orthopyroxene predominate in tephra erupted from the Okataina Volcanic Centre over the same period (Lowe et al. 2008).

In some cases an individual tephra can be identified using distinctive, diagnostic marker minerals, such as aegirine and aenigmatite in the Tuhua Tephra that were erupted from peralkaline Mayor Island volcano c. 7,000 cal. year BP in New Zealand. However, the absence of diagnostic minerals does not necessarily negate correlation because minerals such as olivine, biotite, and hypersthene can be dissolved comparatively quickly in some very acid peat bogs (within 700 years; Hodder et al. 1991) or in soil-forming environments (Lowe 1986; Churchman and Lowe 2012). Ferromagnesian minerals and Fe-Ti oxides also tend to be sparse or absent at distal localities, dropping out from proximal or medial ash clouds earlier because of their high density (Juvigné and Porter 1985).

Although of limited application, the crystal geometry (crystal width) of apatite (a phosphate-group mineral) was shown to be useful, along with apatite trace-element data, for differentiating beds in a study of Late Ordovician K-bentonites in the USA by Sell and Samson (2011). Similarly,

Donoghue et al. (1991) showed that two distinct crystal geometries of olivine (skeletal, non-skeletal) were useful in correlating some andesitic tephra in New Zealand.

Major-Element Analysis of Glass Shards, Melt Inclusions, and Minerals

The electron microprobe enables a range of tephra components to be analyzed for major elements on a grain-by-grain basis: individual glass shards, glassy coatings on crystals, melt inclusions (glass preserved within crystals including quartz, pyroxenes, amphiboles), pumice fragments, and loose crystals or phenocrysts including various ferromagnesian silicate minerals, apatite, zircon, and Fe-Ti oxides such as titanomagnetite (Table 1). The main advantage of the microprobe and other single-grain techniques is that they allow mixed or heterogeneous populations to be identified. Because volcanic glass is amorphous, its analysis by microprobe needs especially careful sample preparation and mounting, the use of appropriate standards, and optimum probe-operating conditions to derive accurate and robust data (Kuehn et al. 2011; Hall and Hayward 2014; Pearce et al. 2014; Suzuki et al. 2014).

Usually a defocused (e.g., 10–20 μm) or rastered beam is deployed to minimize the mobilization of Na, although protocols that use narrower beam diameters (3–5 μm) without loss of Na have been recently developed for analyzing fine-grained glass shards, as occur in distal or ultra-distal tephra or cryptotephra or glasses with microlites (Hayward 2012; Pyne-O'Donnell et al. 2012; Hall and Hayward 2014). Glass microprobe analyses are usually normalized (summed to 100 %, most, but not all, of the deficit being attributable to water) to enable useful comparisons of analyses (Shane 2000; Lowe 2011; Westgate et al. 2013a). Using stratigraphic or age constraints, and usually also a knowledge of geochemical affinities of potential source rocks/deposits and spatial distribution patterns, the microprobe analysis of glass may allow tephra source volcanoes to be identified, and individual eruptives may also be correlated in some cases where compositions through time have changed from one eruptive event to the next. Complexities arise where glass analyses show heterogeneity, a consequence potentially of (i) mingling or mixing of separate batches of magmas that were tapped simultaneously or sequentially as eruptions proceeded (e.g., Tryon et al. 2010; Turner et al. 2011b), (ii) major-element evolution by fractional crystallization or crustal assimilation (Bogaard and Schminke 1985; Ukstins Peate et al. 2008; Óladóttir et al. 2012), (iii) blending of thin tephra in soil-forming or cryogenic environments (Lowe 1986; Eden et al. 2001; Dugmore and Newton 2012), or (iv) post-depositional dissemination of glass shards in peat, lake, or marine sediments (Gehrels et al. 2006; Allan et al. 2008; Abbott et al. 2013). Heterogeneity arising from magmatic or volcanic eruption processes accompanied by changes in wind direction warns of the difficulty of characterizing (thus fingerprinting) tephra beds using a limited set of distal samples from restricted dispersal sectors (Shane et al. 2008a). Another problem can arise with analyses of melt inclusions where these do not reflect the full compositional range of glass shards or matrix glass (e.g., Shane et al. 2008b; Chesner and Luhr 2010; Allan et al. 2013) or they show a pattern different from that associated with matrix glass analyses (e.g., Kilgour et al. 2013). Once recognized, such compositional variability can enhance correlation by providing additional fingerprinting criteria, but sampling from the full spatial and temporal range of deposits of an eruptive sequence is required (Alloway et al. 2013).

The correlation of andesitic or basaltic tephra using glass chemistry generally can be complicated for various reasons including the multiplicity of units, the paucity of suitable glass for microprobing (shards may contain micro-inclusions and can be highly vesicular), susceptibility of glass to weathering, and wide compositional ranges and potential heterogeneity as noted previously (Moebis et al. 2011; Shane and Zawalna-Geer 2011; Óladóttir et al. 2012). Platz et al. (2007) provided a procedure to evaluate glass compositional variability arising from the inadvertent

microanalysis of plagioclase microlites in shards using a wide beam, but the recent use of narrower beam diameters is helping to obviate this problem (Hayward 2012; Pearce et al. 2014).

Analyses by microprobe of ferromagnesian silicate minerals, such as biotite (Shane et al. 2003; Smith et al. 2011) and cummingtonite (Matsu'ura et al. 2012), apatite (a phosphate-group mineral) (Sell and Samson 2011), and Fe-Ti oxides such as titanomagnetite and ilmenite (Shane 1998; Preece et al. 2011b; Marcaida et al. 2014), have also been used for tephra fingerprinting. In some cases, and after taking into account compositional zoning within crystals, trace elements such as Mg, Cl, Mn, Fe, Ce, and Y identified in apatite crystals and phenocrysts provide a means of distinguishing or matching tephras (Sell and Samson 2011). The eruption temperature and oxygen fugacity (oxidation state of magma) of rhyolitic tephras – estimated using single-grain EMPA of Fe-Ti oxide pairs of titanomagnetite and ilmenite – provide another way to correlate tephras and, in some cases, magma batches within an eruptive sequence (Smith et al. 2005; Preece et al. 2011b; Marcaida et al. 2014).

Trace-Element and Isotope Analysis of Glass

Although the microprobe is now the key analytical tool for undertaking major-element analyses of glass, tephras or cryptotephras cannot always be distinguishable uniquely by major-element data alone. In these cases, other analytical methods are needed (Westgate et al. 2013c). Trace-element analyses of glass separates from tephra or cryptotephra deposits offer a greater range of elements for use in correlation/provenance studies and may also provide additional information on volcanic petrogenesis. In the last decade, trace-element techniques have become more common, the most widely available being laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) (e.g., Albert et al. 2012; Ponomareva et al. 2013a; Sulpizio et al. 2013) (Table 1). Pearce (2014) provides protocols for the application of LA-ICP-MS to glass shards. Around 150 individual glass shards can be analyzed for about 30 trace elements in 1 day using LA-ICP-MS (Pearce et al. 2011). Comprehensive studies using this method were undertaken on Pleistocene tephras in northern New Zealand (Pearce et al. 2008b) and in marine cores from Ocean Drilling Project (ODP) Site 1123 (Allan et al. 2008). The most useful elements for correlating and distinguishing between the ODP Site 1123 tephras were found to be the abundances of Rb, Ba, Sr, Y, Zr, Hf, Mg, Mn, and Ti and trace-element ratios including Rb/Sr, Ba/Sr, Zr/Y, Y/Th, Ba/Th, and Rb/Sm. Using trace-element data for glass shards, Allan et al. (2008) demonstrated that (i) tephras with similar major-element compositions (e.g., Kawakawa tephra vs. Omataroa tephra) were easily distinguishable (Fig. 7) and (ii) two previously unidentified repeated sections of ODP cores 1123A (~4.5 m thick) and 1123C (~7.9 m thick) were recognized (Allan et al. 2008). As with the microprobe, there is a possibility of microlites affecting trace-element characterizations of individual shards via LA-ICP-MS, and so anomalous assays need to be evaluated carefully (Abbott et al. 2013).

Analyses of isotopes of Sr, Nd, and Pb in glass (or pumices) have been utilized in several studies to help determine tephra source volcanoes (e.g., Roulleau et al. 2009; Westgate et al. 2008, 2011; Giaccio et al. 2013).

Comparing Compositional Data Using Graphical, Numerical, and Statistical Methods

Major- or trace-element datasets obtained from analyses of glass or minerals may be displayed and compared, and hence compositional variability evaluated, using various methods: graphical (e.g., bivariate or trivariate plots), numerical (e.g., similarity coefficients), or statistical (e.g., statistical distance measure, dendrograms, discriminant function analysis, principal components analysis) (Pearce et al. 2008a; Bourne et al. 2010; Lowe 2011; Sell and Samson 2011). In many cases, the bivariate plots alone can provide sufficient guidance to enable anomalous data points to be identified

Fig. 7 Bivariate plots for some major and trace elements derived from analyses of individual glass shards from two New Zealand tephra, Omataroa (c. 31,600 cal. year BP, erupted from Okataina Volcanic Centre) and Kawakawa (c. 25,400 cal. year BP, erupted from Taupo Volcanic Centre), identified in marine cores (a), (b), and (c) from ODP Site 1123 about 1,200 km east of New Zealand (Modified after Allan et al. 2008, p. 2351, with permission of Elsevier). (a) CaO versus FeO_t (total iron expressed as FeO) derived by electron microprobe. Glass analyses from an onshore occurrence of Kawakawa tephra (at Irirangi) are also shown for comparison. The plot shows that the analyses of marine and onshore samples of Kawakawa tephra are identical and that Kawakawa and Omataroa tephra cannot be distinguished using these two oxides alone. In contrast, trace-element concentrations (in ppm), derived by LA-ICP-MS, in (b) and (c), show that the tephra are distinctly different with respect to their elements/element ratios and hence can be readily distinguished

(and possibly explained using compositional databases for comparison) and potential correlations or otherwise established with reasonable likelihood, especially where multiple criteria provide independent support, such as concordance of glass major- and trace-element data together with Fe-Ti oxide data (e.g., see Preece et al. 1999, 2011b). In other situations, however, statistical methods such as principal components analysis can allow units to be distinguished objectively on the basis of multiple oxides or elements (not just two or three) analyzed from glass shards or crystals (e.g., Tryon et al. 2010; Chiasera and Cortés 2011; Sell and Samson 2011).

Dating Tephra (Tephrochronometry)

Tephra may be dated directly using primary minerals (e.g., zircon, hornblende, K-feldspars, biotite, quartz) or glass from within the tephra layer, or indirectly on either enclosing or encapsulated material, using a range of methods including radiometric, incremental (e.g., varves, layering in ice), and age equivalence (Table 2) (Svensson et al. 2008; Alloway et al. 2013; Zalasiewicz et al. 2013). These ages can then be transferred from one site to another where the tephra is recognized using the

Table 2 Methods used for dating tephtras directly or indirectly (after Lowe 2011)

Main method	Applications
Radiometric	Radiocarbon dating (radiometric/beta counting, AMS) ^a Fission-track dating of zircon or glass-ITPFT or glass-DCFT dating Argon isotopes (K/Ar, Ar/Ar including SCLP/F, LIH) Luminescence dating (TL, OSL, IRSL, pIR-IRSL) U-series including (U-Th)/He, U-Pb, and ²³⁸ U/ ²³⁰ Th zircon dating (SIMS/TIMS, SHRIMP, LA-ICP-MS) Electron spin resonance ²¹⁰ Pb, ¹³⁷ Cs, ³ He, and ²¹ Ne surface exposure dating
Incremental	Dendrochronology, varve chronology, layering in ice cores (ice sheets/caps, glaciers)
Age equivalence	Magnetopolarity, paleomagnetic secular variation, astronomical (orbital) tuning, correlation with marine oxygen isotope stages, climatostratigraphy, biostratigraphy, palynostratigraphy, paleopedology
Age modeling	Various age-depth methods including Bayesian flexible depositional modeling and wiggle matching, spline-fit modeling
Relative	Obsidian hydration dating, amino acid racemization
Historical	Eyewitness accounts or observations (e.g., via remote sensing)

^aAMS accelerator mass spectrometry, *ITPFT* isothermal-plateau fission track, *DCFT* diameter-corrected fission track, *SCLP/F* single-crystal laser probe or fusion, *LIH* laser incremental heating, *TL* thermoluminescence, *OSL* optically stimulated luminescence, *IRSL* infrared stimulated luminescence, *pIR-IRSL* post infrared-infrared-stimulated luminescence, *SIMS* secondary ionization mass spectrometry, *TIMS* thermal ionization mass spectrometry, *SHRIMP* sensitive high-resolution ion microprobe, *LA-ICP-MS* laser ablation inductively coupled plasma mass spectrometry

lithostratigraphic and compositional-based methods described above. Only the main radiometric methods, and age modeling, are touched on here.

For tephtras erupted within the past c. 60,000 calendar years, the radiocarbon (¹⁴C) technique (e.g., Hogg et al. 2007) remains the most important method for developing calibrated age models. In recent years, the advantages of using pollen concentrates and terrestrial plant macrofossils (e.g., leaves, twigs), rather than bulk organic samples, as reliable dating materials via AMS have been demonstrated (Newnham et al. 2007; Staff et al. 2011). Together with dendrochronological wiggle-matching methods (Hogg et al. 2012; Yin et al. 2012), Bayesian flexible depositional age modeling has added a revolutionary aspect to the construction of enhanced and more precise chronologies in tephrochronology involving ¹⁴C and other dating methods (Blockley et al. 2008; Smith et al. 2013). Lowe et al. (2013) dated late Quaternary tephtras in New Zealand by modeling ¹⁴C age data using two Bayesian-based programs, Bacon (Blaauw and Christen 2011) and OxCal's *P_Sequence* function (Bronk Ramsey 2009) and the IntCal09 dataset (Fig. 8). Lohne et al. (2013) also used *P_Sequence* and IntCal09 to obtain high-precision ages of 12,066 ± 42 and 10,210 ± 35 cal. year BP (±1σ) for the Vedde and Saksunarvatn tephtras, respectively, from sediments in Kråkenes Lake, Norway. Similarly, the AT tephtra of Japan was dated to 30,009 ± 189 cal. year BP (95 % probability) using *P_Sequence* modeling of ¹⁴C data and varves (Smith et al. 2013). Vandergoes et al. (2013) used OxCal's *Tau_Boundary* function, also Bayesian, to precisely date the Kawakawa/Oruanui tephtra of New Zealand to 25,358 ± 162 cal. year BP (95 % probability).

Another key advance in tephrochronology has been the development of the isothermal-plateau fission-track dating method (ITPFT) for glass (Westgate 1989; Alloway et al. 2004b, 2013; Westgate et al. 2013b). ITPFT and the diameter-corrected fission-track method (Sandhu and Westgate 1995) have enabled ages to be obtained on many distal vitric-rich tephtras that previously were unable to be dated because of low abundance of dateable mineral constituents, fine grain size, and the presence of detrital grains. Examples of such applications include dating Quaternary glacioeustatic sedimentary

Fig. 8 Bayesian-derived age models (95 % probability) for nine late Quaternary tephras in New Zealand (From Lowe et al. 2013, p. 179, with permission of Elsevier). Probability plots are colored according to tephra source volcanoes: *red*, Okataina; *orange*, Taupo; *green*, Taranaki; and *blue*, Tongariro. Gray plots show the start and end ages of the late glacial cool episode, designated climate event NZce-3 by Barrell et al. (2013), in part constrained chronologically by the ages on the adjacent tephras

cycles in the Wanganui Basin (Alloway et al. 1993; Pillans et al. 2005) and dating initial loess deposition in Alaska at ~3 million years ago (Westgate et al. 1990). The glass-FT techniques have been used, for example, also to test chronologies based on alternative methods (such as magnetic polarity and astronomical tuning) for marine tephra sequences (Alloway et al. 2005; Allan et al. 2008) and for fossiliferous alluvial and lacustrine sediments in Beringia (Preece et al. 2011b; Westgate et al. 2013a).

Where suitable minerals are available (e.g., sanidine, biotite, leucite, anorthoclase), the $^{40}\text{Ar}/^{39}\text{Ar}$ method has been useful, such as dating the Laacher See tephra in Germany (Bogaard 1995); the ultra-distal to distal deposits of the Youngest Toba Tuff tephra of Indonesia (Westgate et al. 1998; Storey et al. 2012); a widespread Holocene tephra erupted from Ulleungdo stratovolcano in South Korea (Smith et al. 2013); a 400,000-year-old sequence of eruptives from Nemrut volcano preserved in Lake Van, eastern Anatolia in Turkey (Sumita and Schminke 2013); and the distal tephras preserved in lacustrine and fluvial sediments of intermontane basins of central Italy (Giaccio et al. 2013). A relatively new method for dating proximal pyroclastic deposits, previously applied to petrologic studies, is the use of U-Pb analyses to date zircons (Schmitt 2006; Dickinson et al. 2010; Wilson et al. 2010). Luminescence and (U-Th)/He dating methods are also being applied systematically to tephra deposits (Danišik et al. 2012; Biswas et al. 2013).

A trend in dating lake sediment sequences containing tephras or cryptotephra is to apply multiple methods, as exemplified by Staff et al. (2013) and Sirocko et al. (2013).

Conclusions

Tephrochronology is the use of primary tephra or cryptotephra as isochrons to link and synchronize geological, paleoenvironmental, or archaeological sequences or events, or soils, and, uniquely,

to transfer relative or numerical ages to them using stratigraphic information and mineralogical and geochemical compositional data, especially from individual glass-shard analyses, obtained for the tephra/cryptotephra. To function therefore as an age-equivalent correlation and chronostratigraphic dating tool, tephrochronology can be undertaken in three steps: (i) mapping and describing tephra and determining their stratigraphic relationships, (ii) characterizing tephra or cryptotephra in the laboratory, and (iii) dating them using a wide range of geochronological methods. Tephrochronology is also an important tool in volcanology, informing studies on volcanic petrology, volcano eruption histories and hazards, and volcano-climate forcing. Although limitations and challenges remain, multidisciplinary applications of tephrochronology continue to grow markedly (e.g., Alloway et al. 2013; Lane et al. 2014).

Acknowledgments

We thank editors Jeroen Thompson and Jack Rink for inviting us to write this entry and for their suggestions, reviewer Vera Ponomareva for her helpful comments, Megan Balks and Adam Brumm for providing photographs, and Chris Hayward and John Westgate for furnishing preprints. Elsevier kindly allowed us to use previously published material (Figs. 7 and 8). The entry was funded in part by the New Zealand Marsden Fund (project 10-UOW-056 to DJL entitled “New views from old soils”), administered by the Royal Society of New Zealand, and it is an output also of the INTREPID Tephra-II project (INQUA project 1307s) “Enhancing tephrochronology as a global research tool through improved fingerprinting and correlation techniques and uncertainty modeling (phase II),” an initiative of the International Focus Group on Tephrochronology and Volcanism (INTAV) supported by the Stratigraphy and Chronology Commission of the International Union for Quaternary Research (INQUA).

Kimberlites (K-Ar/Ar-Ar)

David Phillips*

School of Earth Sciences, The University of Melbourne, Parkville, VIC, Australia

Synonyms

⁴⁰Ar/³⁹Ar geochronology; Conventional K–Ar dating; K–Ar dating; Kimberlite clan rocks

Definitions

Potassium-argon (K–Ar) dating: Scientific dating method based on the natural decay of ⁴⁰K to ⁴⁰Ar, where the ratio of the parent isotope, ⁴⁰K, relative to the daughter product ⁴⁰Ar (radiogenic ⁴⁰Ar or ⁴⁰Ar*) is used to calculate the age of a sample.

⁴⁰Ar/³⁹Ar (Argon-Argon) geochronology: A variation of the K–Ar method, where the ⁴⁰K content is determined indirectly by neutron activation of ³⁹K to ³⁹Ar; here, the ⁴⁰Ar* to ³⁹Ar ratio is proportional to age, with sample ages calculated relative to co-irradiated standards of known age.

Excess argon: ⁴⁰Ar, aside from atmospheric ⁴⁰Ar, that is incorporated into rocks and minerals by processes other than in situ radioactive decay of ⁴⁰K. Excess argon results in ⁴⁰Ar to ³⁶Ar > 295.5 and may be identified from isochron plots.

Inherited argon: Radiogenic argon (⁴⁰Ar*) included in rocks and minerals through contamination by older material or retention of ⁴⁰Ar* from a previous event, e.g., feldspar xenocrysts in extrusive volcanic rocks that are not isotopically reset by the magmatism and retain some proportion of the ⁴⁰Ar* generated between the times of xenocryst crystallization and magma eruption.

Extraneous argon: A *sac* term for excess or inherited argon.

Kimberlites (Definitions modified from Mitchell (1986)): Small volume, volatile-rich, potassic ultramafic igneous rocks that usually occur as diatremes, but also as dykes and sills and sometimes contain diamonds. Kimberlites typically have an inequigranular texture due to abundant crustal and mantle fragments set in a fine-grained matrix. Two varieties are recognized:

- i. *Group I kimberlites*: CO₂-rich, potassic ultramafic igneous rocks with an inequigranular texture. Megacryst/macrocryst minerals include olivine, ilmenite, pyrope garnet, phlogopite, enstatite, and chromite. Matrix minerals include olivine, phlogopite, perovskite, spinel, diopside, monticellite, apatite, calcite, and serpentine.
- ii. *Orangeites (or Group II kimberlites)*: H₂O-rich, ultrapotassic, peralkaline igneous rocks, often with an inequigranular texture. Megacryst/macrocryst minerals include phlogopite,

*Email: dphillip@unimelb.edu.au

olivine, pyrope garnet, enstatite, and chromite. Matrix minerals typically include abundant phlogopite and lesser clinopyroxene, spinel, perovskite, apatite, REE-phosphates, K-Ba-titanates, rutile, and ilmenite. More evolved orangeites may contain matrix sanidine, K-richterite, and Zr-silicates.

Lamproites (Definition modified from Mitchell (1995)): Small volume, peralkaline, ultrapotassic igneous rocks that occur as diatremes, cinder cones, dykes, and sills. Megacryst/macrocryst minerals include olivine, pyrope garnet, phlogopite, enstatite, and chromite. Minerals typical of lamproites include leucite, titanian phlogopite phenocrysts, titanian tetraferriphlogopite, Ti-K-richterite, diopside, sanidine, K-Ba-titanates (e.g., priderite), and K-Zr-silicates (e.g., wadeite).

Introduction

Kimberlites and related rocks are volumetrically insignificant igneous rocks but have received considerable scientific attention because they are a primary host rock for diamonds and contain a large range of xenoliths (rock fragments) from the underlying crust and mantle. Kimberlites and related rocks have proven difficult to date accurately, due to their propensity to alteration and the almost ubiquitous presence of crustal and mantle xenolithic material. Over the years, several scientific dating methods have been applied to kimberlite geochronology, including the K-Ar, $^{40}\text{Ar}/^{39}\text{Ar}$, U-Pb, Rb-Sr, and fission track methods. Currently, the most widely applied techniques involve Rb-Sr dating of phlogopite and U-Pb dating of perovskite methods (see reviews by Allsopp et al. 1989 and Heaman et al. 2003). The K-Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ techniques (for information on these methods, see McDougall and Harrison 1999) are less commonly employed, due to the common presence of extraneous argon (excess or inherited argon) in kimberlitic minerals (e.g., phlogopite), which results in anomalously old ages. Nonetheless, the $^{40}\text{Ar}/^{39}\text{Ar}$ dating method can provide useful kimberlite and related rock age information, provided that samples are carefully chosen and appropriate experimental procedures are employed to test for extraneous argon (Phillips et al. 1998, 1999; Phillips et al. 2012a).

Historical Development

The earliest attempts to date kimberlitic rocks using the K-Ar dating method focused on kimberlites located in Kentucky and Kansas. These studies targeted large phlogopite grains (megacrysts), which yielded variable age results that were difficult to interpret (Zartman et al. 1967; Brookins 1969; Brookins and Naeser 1971). Many subsequent attempts to date kimberlites using conventional K-Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating methods also utilized large phlogopite macrocrysts or phlogopite-bearing mantle xenoliths (e.g., Macintyre and Dawson 1976; Kaneoka and Aoki 1978). Although reliable K-Ar ages consistent with stratigraphic or other isotopic evidence were reported for some kimberlitic phlogopite samples, most coarse phlogopite grains produced anomalously old K-Ar or $^{40}\text{Ar}/^{39}\text{Ar}$ ages as well as disturbed ^{40}Ar – ^{39}Ar step-heating spectra (see reviews by Phillips et al. 1999; Phillips 2012).

The anomalously old ages are consistent with crystallization of phlogopite macrocrysts/megacrysts prior to kimberlite eruption, and are usually attributed to the presence of inherited argon, although some authors also invoked the presence of excess argon to explain some results

Fig. 1 Photomicrograph showing euhedral, matrix phlogopite grains in a magmatic kimberlite. Note the presence of other matrix mineral (e.g., spinel) inclusions in the phlogopite grains, confirming a magmatic paragenesis. The field of view of the photomicrograph is 2 mm

(see reviews by Phillips 1991, 2012; Hopp et al. 2008). Allsopp and Roddick (1984) conducted the first systematic study to compare $^{40}\text{Ar}/^{39}\text{Ar}$ results from large phlogopite macrocrysts and groundmass phlogopite grains extracted from the Dokolwayo orangeite in Swaziland. This study obtained older apparent $^{40}\text{Ar}/^{39}\text{Ar}$ ages from large phlogopite macrocrysts, but concordant (plateau) age results for groundmass phlogopite crystallized from the orangeite magma. Consequently, more recent studies have focused on matrix phlogopite grains, which, if unaltered, can provide reliable age results for kimberlite magmatism (see Phillips et al. 1998, 1999; O'Brien et al. 2007; Phillips et al. 2012a).

Key Concepts

Sample Selection and Characterization

Phlogopite mica is the preferred mineral for K-Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating of kimberlites and related rocks, due to its common occurrence and relatively high K content (~8 wt%). Phlogopite occurs in these rocks as primary and secondary grains in entrained mantle xenoliths, as megacrysts and macrocrysts (crystal fragments) and as groundmass crystallites of the kimberlite and related rock melts (Mitchell 1986, 1995). Orangeites and lamproites also contain other potassium-bearing minerals that may be suitable for K-Ar or $^{40}\text{Ar}/^{39}\text{Ar}$ dating, such as sanidine, K-richterite, K-Ba-titanates, and K-Zr-silicates (Jaques et al 1984; Phillips et al. 2012a); however, few studies have been conducted on these phases.

Careful sample selection and characterization is key to obtaining reliable $^{40}\text{Ar}/^{39}\text{Ar}$ ages for kimberlites and related rocks because of the presence of extraneous argon in phlogopite xenocrysts and phenocrysts. Therefore, petrographic characterization of kimberlite and related samples is a minimum requirement for identifying samples hosting suitable matrix phlogopite (or other K-bearing magmatic minerals). The best material for $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology is fresh groundmass phlogopite that is sufficiently coarse grained ($>100\text{ }\mu\text{m}$) to allow routine mineral separation; these grains are usually restricted to magmatic kimberlite and related rock occurrences (e.g., dykes and sills). Volcaniclastic samples are generally unsuitable, due to fine grain sizes, heterogeneous mineral populations, and susceptibility to alteration.

Fig. 2 $^{40}\text{Ar}/^{39}\text{Ar}$ step-heating age spectra obtained on individual matrix tetraferriphlogopite grains from the Voorspoed kimberlite, South Africa (Modified from Phillips et al. 1998). Aside from a few discordant low temperature results, most steps show concordant results, averaging 131.5 ± 1.6 Ma (2σ). Note: each *color* represents a separate step-heating experiment on a single phlogopite grain; the *boxes* represent individual step-heating analyses, with the width indicating the relative proportion of ^{39}Ar released and bar heights indicating plus/minus one sigma uncertainties

Where present, magmatic (i.e., matrix) micas in Group I kimberlites belong to the kinoshitalite compositional series. Orangeites and lamproites typically contain abundant, euhedral tetraferriphlogopite groundmass crystals (Fig. 1). In thin section, matrix phlogopite grains may be distinguished from xenocrysts/phenocrysts by their finer grain size and the common presence of inclusions of other groundmass minerals such as spinel (see Fig. 1). In cases where matrix phlogopite is uncommon (e.g., many Group I kimberlites), more effort is usually required to locate rare matrix minerals or phlogopite associated with reaction rims on garnets or other xenocrysts (Phillips et al. 2012b). Once phlogopite mineral separates are obtained, it is desirable to analyze a number of single phlogopite grains using the $^{40}\text{Ar}/^{39}\text{Ar}$ step-heating method to assess age reliability (see below).

$^{40}\text{Ar}/^{39}\text{Ar}$ Geochronology of Kimberlites and Related Rocks

As noted, the attainment of reliable $^{40}\text{Ar}/^{39}\text{Ar}$ age data for kimberlites and related rocks is dependent on the selection of suitable, unaltered, magmatic minerals such as matrix phlogopite. Despite the fine grain size of matrix phlogopite grains ($<200\ \mu\text{m}$), the advent of microanalytical $^{40}\text{Ar}/^{39}\text{Ar}$ laser-probe dating techniques (e.g., Phillips et al. 1998, 1999) permits step-heating analyses of single groundmass phlogopite grains (or aliquots of a few grains). This approach avoids problems associated with bulk mineral separates, such as contamination by phlogopite xenocrysts and phenocrysts hosting extraneous argon, and also allows assessment of other potential problems such as thermal- or alteration-induced argon loss and recoil effects (see Hall (2013) for a discussion of recoil effects). An example of an $^{40}\text{Ar}/^{39}\text{Ar}$ experiment conducted on single matrix tetraferriphlogopite grains ($\sim 200\ \mu\text{m}$ in size) from the Voorspoed orangeite (South Africa) is shown in Fig. 2 (see Phillips et al. 1998 for details). In this case, three phlogopite grains were

individually step-heated in 3–6 increments. Aside from minor discordance associated with the lowest temperature steps, all three grains show reproducible results, with a weighted mean age 131.5 ± 1.6 Ma (2σ). This and other examples (see Phillips et al. 1999) demonstrate the high precision capability of the $^{40}\text{Ar}/^{39}\text{Ar}$ laser-probe method, provided that suitable sample material is available.

Sediment Mixing Rate, ^{210}Pb and ^{234}Th

Joseph M. Smoak*

Department of Environmental Science, Policy and Geography, University of South Florida, St. Petersburg, FL, USA

Definition

Sediment mixing – the movement or redistribution of deposited sediments within a sediment column by physical and/or biological means such that the sediment is moved from its original sequence or position of deposition.

Introduction

Two members of the naturally occurring uranium and thorium decay series, ^{210}Pb (half-life 22.3 years) and ^{234}Th (half-life 24.1 days), may occur in excess of their parent activity at depth within the sediment column of aquatic systems either from sediment accumulation or downward mixing of sediment particles. The downward mixing of sediment particles is produced by physical processes such as current or wave action and biological processes such as burrowing organisms. Being aware of and understanding sediment mixing is important for several reasons. The most basic of these reasons relates to using sediments to interpret the past. Sediments are deposited in sequential order and thus provide a temporal record of surface processes and a historical record of material input. This information can have a variety of uses from understanding past climate or environmental changes to reconstruction of the pollution or contaminant history of a drainage basin. Interpreting the sequential sediment record or layers is sometimes described by the analogy of reading the layers like they are pages in a book. Now imagine the pages in the book have been rearranged. This rearrangement alters or smears the sediment record which can influence the preservation of physical sedimentary structures (Nittrouer and Sternberg 1981). How much the sediment record is altered depends on the intensity, depth, and nature of the sediment mixing in relation to the sediment accumulation rate (Smoak and Patchineelam 1999). Sediment mixing also influences degradation and preservation of biogenic components, pore-water concentrations of dissolved chemical species within the sediment mixed layer (Schink and Guinasso 1977; Berner 1980; Aller 1982; Alperin et al. 1999), microbial activity (Yingst and Rhoads 1980), and fate and transport of contaminants (Bothner et al. 1980; Officer and Lynch 1989).

In marine systems, both ^{210}Pb and ^{234}Th are continually produced within the overlying water column by their radionuclide parents, while ^{210}Pb is also supplied via atmospheric fallout. In freshwater systems, ^{234}Th may not be present, and ^{210}Pb supply may be dominated by the atmospheric fallout due the low abundance of the radionuclide parents within the water column. In either case once in the water column, ^{210}Pb and ^{234}Th interact with particles and are rapidly removed from dissolved to particulate phase. Due to the rapid adsorption onto particles, these elements along with other elements that rapidly become particle bound are referred to as “particle-reactive” elements. Once in the particulate phase, the particles to which they are attached may settle from the water column and be deposited at the sediment/water interface. The occurrence of excess

*Email: smoak@mail.usf.edu

^{210}Pb or ^{234}Th in the sediments deeper than would be produced by sediment accumulation alone can be used to characterize sediment mixing. While physical and biological mixing are separate processes, they may both occur within the same sediment column. However, most systems can be characterized as mixed by either dominantly physical or biological processes depending on the preservation of primary sedimentary structure. Physical mixing by waves, tides, and currents is generally event driven and potentially resets the sediment record within the mixing zone (Sanford 1992) while preserving sedimentary structure below the mixing zone. Biological mixing, referred to as bioturbation, is generally a steady-state process that can destroy the sedimentary structure (Dellapenna et al. 1998) depending on the mixing rate compared to accumulation rate. The radioactivity profiles of ^{210}Pb or ^{234}Th produced by sediment mixing are often used to calculate diffusion coefficients based on Fick's law of diffusion. The diffusion coefficient is defined as the rate at which the variance of particle location changes with time, where the variance is a measure of particle spread and is proportional to the squared velocity of the diffusing particle (Crank 1975). The coefficient units are length squared per unit time typically expressed as $\text{cm}^2\text{-yr}^{-1}$.

Most attempts to model sediment mixing have been used to evaluate biological mixing; however, the same models have been applied to physical mixing as well. The coefficients produced by biological mixing are referred to as biodiffusion coefficients although they are actually eddy diffusion coefficients. Biological sediment mixing is not truly a diffusive process; however, in many cases, biological mixing appears diffusive-like when many nondiffusive events are integrated over a short time period compared to the time scale of the radioactive tracer (Aller and Dodge 1974; Robbins et al. 1979; Boudreau 1986; Wheatcroft et al. 1990; Maire et al. 2008). If mixing is not rapid compared to the time scale of the tracer, tracer-dependent artifacts can appear (Reed et al. 2007; Lecroart et al. 2010). For a diffusion model to accurately represent the physical process of sediment mixing, sediment particles must be moved in a random manner over short distances. Large step length in the advection of sediment produced by conveyor belt-type sediment feeders may violate these assumptions. Nonrandom movement produced by selective feeding due to size, shape, texture, or composition may also violate these assumptions (Smoak and Patchineelam 1999). A one-dimensional biodiffusion model is the most commonly applied model due to its simplicity. Even though the assumptions may be violated and the model does not include realistic biological complexity, an accurate empirical model is produced in most cases. The fact that the model is used despite these issues has been referred to by Meysmann et al. (2003) as the "biodiffusion paradox." Other more complex and realistic models have been developed for different types of reworking using nonlocal transport models (Francois et al. 1997, 2001; Boudreau and Imboden 1987; Meysman et al. 2003; Maire et al. 2007). For a complete review of methods to quantify bioturbation rates, refer to Maire et al. (2008).

Sediment Mixing Model

Despite the fact that assumptions are often violated, sediment mixing is generally well described by a simple one-dimensional diffusion model based on Fick's law of diffusion. This is the most commonly used model to calculate diffusion coefficients. Activity (A ; dpm-g^{-1}) of the tracer in the sediment column will be affected by the sediment mixing (D ; $\text{cm}^2\text{-yr}^{-1}$), sediment accumulation (S ; cm-yr^{-1}), radioactive decay (λ ; yr^{-1}), and production (P ; $\text{dpm-g}^{-1}\text{-y}^{-1}$) of these radionuclides supported by their parents. All of these variables influence the observed tracer profile in the sediment column and are all included in the steady-state equation Eq. (1) presented by Guinasso and Schink (1975) where z is depth below the sediment-water interface.

$$D \frac{\partial^2 A}{\partial z^2} - S \frac{\partial A}{\partial z} - \lambda A + P = 0 \quad (1)$$

Using the excess activity allows the production term to be removed, and diffusion coefficients can be obtained from the following steady-state equation Eq. (2):

$$A_z = A_0 \exp\left(\frac{S - \sqrt{S^2 + 4D\lambda}}{2D} z\right) \quad (2)$$

In Fig. 1 Eq. (2) was used to create an idealized plot showing the activity of the tracer as a percent of the initial activity versus depth. In this plot the sediment accumulation rate is 2 mm-yr^{-1} , diffusion coefficient is $35 \text{ cm}^2\text{-yr}^{-1}$, and the mixed depth is 10 cm. The longer-lived tracer (i.e., ^{210}Pb) has a nearly vertical profile within the mixed layer, while the shorter-lived tracer (i.e., ^{234}Th) exhibits a strong gradient. In this case the ^{234}Th profile is dominated by mixing, and a simplified version of the equation Eq. (3) can be used to calculate the diffusion coefficient. This approach is commonly applied within the mixed zone by fitting a regression line to the activity profile of the tracer and using the gradient to calculate the diffusion coefficient (D).

$$D = \lambda \left[\frac{z}{\ln(A_0/A_z)} \right]^2 \quad (3)$$

In cases where accumulation and mixing rates are much slower, ^{210}Pb can be used in the same way ^{234}Th was used above to calculate diffusion coefficients.

Fig. 1 Idealized plot showing the activity of the tracer as a percent of the initial activity versus depth (cm). Sediment accumulation rate is 2 mm-yr^{-1} , diffusion coefficient is $35 \text{ cm}^2\text{-yr}^{-1}$, and the mixed depth is 10 cm

Conclusion

Sediment mixing, either physically and/or biologically induced, results in the alteration of the original location of sediment particles. This sediment mixing, in turn, influences the degree of preservation of the sediment record and biogenic components, microbial activity, and fate and transport of contaminants. The most common approach to modeling sediment mixing is to use a one-dimensional diffusion-type model. The naturally occurring radionuclides ^{234}Th and ^{210}Pb are well-suited tracers to estimate the diffusion mixing coefficient in these models. When mixing is relatively rapid, the shorter time-scale tracer (^{234}Th) is the most suitable. When sediment accumulation and mixing rates are slower, the longer time-scale tracer (^{210}Pb) becomes more useful. While these models do not include all the complexity actually involved in sediment mixing, the models along with these uranium-thorium series tracers do create an accurate empirical representation of sediment mixing.

Uranium-Lead, Diagenetic Processes

E. T. Rasbury*

Department of Geosciences, Stony Brook University, New York, NY, USA

Definitions

Diagenesis – Encompasses all of the processes that create and subsequently change sedimentary rocks after deposition of sediments and up to metamorphism.

Introduction

Uranium (U) has two long-lived isotopes, ^{238}U and ^{235}U , with very different half-lives, which decay through independent radioactive decay chains to lead (Pb), ^{206}Pb and ^{207}Pb , respectively. Because they represent two independent systems that should yield the same age, U–Pb dating (see ► [Uranium-Lead Dating](#)) can be a very powerful dating technique, particularly for detecting geochemical disturbance. Here we are concerned with how diagenesis impacts uranium and lead and particularly how this might impact the potential for U–Pb dating of sedimentary rocks. Our ability to use the U–Pb system for dating sedimentary rocks and/or diagenesis has everything to do with our ability to unravel the paragenesis of sedimentary rocks, as well as the stability of the minerals that might form through a paragenetic sequence. For example, loss or addition of the mineral components making up the rock and whether they contain significant uranium and/or lead dictate whether a meaningful age could be derived by U–Pb analyses. A first step is to consider the origin of sedimentary rocks.

U–Pb Dating of the Primary Constituents of Sedimentary Rocks

Sedimentary rocks can be clastic or chemical, and in terms of U–Pb dating, these present very different scenarios. Clasts are the solid particles derived from the breakdown of preexisting rocks, so an age of the particles in a clastic sedimentary rock would give the age of the parent rock (or perhaps an age that is meaningless if the U/Pb has been changed in those clasts). It is often the case that a variety of ages are produced, for example, in detrital zircon studies (see ► [Uranium-Lead, Detrital Zircon](#)). On the other hand, chemical sedimentary rocks that are formed as ions in solution are precipitated abiotically through oversaturation and/or through biogenic removal of the ions from solutions to create shells. If these chemical components are unaltered with respect to uranium and lead, and have high enough U/Pb ratios, a U–Pb age would give the age of formation, which would also be the age of deposition. A few studies have used U–Pb to date primary marine carbonate components such as fossils (Smith and Farquhar [1989](#); Smith et al. [1994](#); Getty et al. [2001](#); Denniston et al. [2008](#)). A major issue to be addressed with chemical sedimentary rocks is that

*Email: troy.rasbury@sunysb.edu

they are vulnerable to later fluids which may alter the U/Pb and thus disturb the isotope systematics. In the worst case, this would produce a meaningless result; in the best case, it could give the age of the diagenetic alteration.

U–Pb Dating of the Fluids of Diagenesis

For both clastic and chemical sedimentary rocks, as the particles that will eventually be turned into rocks are deposited, the constituent minerals are initially subjected to the fluids they are deposited by and in. Through time and geologic processes, these particles and any subsequent phases that are created will be subjected to various other fluids that may be out of equilibrium with the rock and will therefore alter it. In the near-surface diagenetic realm, these fluids are seawater, meteoric water, and where fluids meet, mixing zones. Meteoric fluids, which result from atmospheric precipitation (rain or snow), are generally dilute and slightly acidic solutions that can therefore be very effective at dissolving labile constituents in exposed rocks, thus acquiring chemical signatures that reflect this interaction. As these fluids recharge aquifers, they continue to evolve chemically through interaction with the rocks they come in contact with. Through time, the meteoric fluids approach a chemical equilibrium with the host rocks, and they inherit isotopic and elemental ratios that reflect the integrated pathway. By the same token, the rocks these fluids interact with inherit isotopic and elemental ratios that reflect the fact that fluids have exchanged with them. Some examples of carbonates that are formed by meteoric fluids that have been dated by U–Pb are cave deposits such as flowstones and stalagmites (Richards et al. 1998; Polyak et al. 2008; de Ruiter et al. 2009; Cliff et al. 2010; Pickering et al. 2011; Woodhead et al. 2012; Woodhead and Pickering 2012; Bajo et al. 2012; Pickering et al. 2013) and paleosol (fossil soil) carbonates such as nodules and rhizoliths (Hoff et al. 1995; Winter and Johnson 1995; Rasbury et al. 1997; Wang et al. 1998; Leeder et al. 2008; Ludvigson et al. 2010). Lacustrine (lake) carbonates have also been shown to have good potential for U–Pb dating (Cole et al. 2005; Druschke et al. 2009).

Carbonate platforms are cemented early through marine cements. During some intervals of Earth history such as the Late Paleozoic, marine cements were aragonite and have high U/Pb ratios. Since aragonite is metastable and is not usually preserved in the rock record, it is important to consider how diagenesis will change the U/Pb ratio (Jones et al. 1995). In some cases, the time of formation of marine cements can be constrained by stratigraphic context and tested against other evidence for the age of the cements such as $^{87}\text{Sr}/^{86}\text{Sr}$ and correlation to dated ash horizons (Becker et al. 2002; Rasbury et al. 2004). When carbonate platforms form in arid environments, saline brines from behind the reef may flow through the buried parts of the platforms and diagenetically alter the carbonates, often forming dolomite. Because U and Mg are excluded from evaporite minerals, evaporated seawater can have high U/Ca and Mg/Ca ratios, producing a fluid that makes “hot” dolomite. Luczaj and Goldstein (2000) obtained U/Pb ages of dolomites from the Hugoton Embayment in the Midcontinent of the USA that were approximately 50 Ma younger than the depositional age of the lower Permian-aged carbonates that had been dolomitized. This study showed the hot dolomite was most likely produced by late Permian evaporative brines, consistent with the abundant late Permian salt that is found in that region.

As clastic sediments are buried, they are compacted and the waters within them are expelled and change through time as the conditions change. In the marine realm, we recognize early diagenesis as changes that take place before or during lithification. Nodules of various types, including phosphates, cherts, and carbonates, may form in this early diagenetic realm and their early formation is recognized by the bending of primary layering around them. One study examined

carbonate nodules with two distinct episodes of formation, both considered early diagenesis and showed that processes that could be called early diagenesis were separated by 35 Ma (Israelson et al. 1996). This is a fascinating view of early diagenesis and also a word of caution for assuming that anything appearing to be early diagenesis is effectively the time of sedimentation.

As sediments are buried, fluids that were trapped within the sediments at the time of sedimentation, for example, seawater, can be squeezed out through compaction, possibly resulting in the dissolution of unstable phases and/or the precipitation of new minerals and eventually turning the sediments into rocks, through processes that are collectively termed lithification. Because these fluids are far from the surface, they are typically low in dissolved oxygen. Iron and manganese are soluble in low-oxygen (reducing) fluids, so geochemists use the presence of these elements in carbonate cements as a way to demonstrate that the cements formed from burial fluids. In addition the presence of iron and manganese in primary constituents such as fossil shells is used as an indication that the shells are diagenetically altered and therefore would not necessarily provide information on the primary fluid. Burial fluids migrate in directions that are controlled by the permeability of the rocks as well as through the influence of hydrologic head, interacting with the rocks and acquiring isotope and element ratios that reflect the integrated interaction pathway. In some cases burial fluids from one formation could mix with fluids from other diagenetic realms, creating a new fluid out of equilibrium with the rock with potential for more diagenetic change. Finally, these resulting rocks may be uplifted through tectonic stresses and perhaps faulted and fractured in the process. This changes the hydrologic head, allowing meteoric fluids to permeate downward and higher temperature burial fluids to move up through the rocks, perhaps facilitated by the fractures that have been created. These changes in hydrology can result in fluid mixing which may produce corrosive fluids that dissolve some constituents and in other cases causing phases to precipitate as fluids become oversaturated and form cements. Veins and geothermal deposits that result from such tectonic events have been dated by U-series disequilibrium (Uysal et al. 2007, 2009, 2011; Nuriel et al. 2012a, b), and there is every reason to believe examples from more ancient tectonic events beyond the range of U-series dating could be dated using U–Pb. This is a frontier in the Earth Sciences. Additionally this renewed tectonic activation could be accompanied by volcanic activity with hot plutonic bodies providing a source of heat that promotes fluid circulation through the rocks, sometimes producing ore deposits. U–Pb dating of carbonates associated with the ore deposits would date the time of ore formation and provide valuable insights into the process(es) responsible for economic deposits (Brannon et al. 1996; Grandia et al. 2000).

Summary: U–Pb Dating of Sedimentary Rocks and Diagenesis

It is often possible to decipher the diagenetic history of a sedimentary rock through petrographic and geochemical investigation. Clastic rocks may have cements that formed early, even during initial deposition, or later through compaction and burial and may have even later crosscutting veins resulting from tectonic processes. Whole-rock analyses of such a rock would give a U/Pb result that is a mix of these processes and would not likely give a meaningful U–Pb age. However, if one could separate out generations of cements based on careful petrographic analyses and if these cement generations had not been altered since formation and have high enough U/Pb ratios to have produced measurable radiogenic Pb, it would be possible to date the diagenetic events. While the application of U/Pb to dating diagenetic phases in clastic sedimentary rocks is rare, numerous studies have investigated other geochemical constraints such as fluid inclusions and oxygen isotopes which can be used to place bounds on the temperature and salinity of the fluids. These phases

are often quite small, on the order of tens of microns, but as techniques such as laser ablation MC-ICP-MS (Multi-Collector Inductively Coupled Plasma Mass Spectrometry) and SIMS (Secondary Ion Mass Spectrometry) continue to be developed, it is likely that U–Pb dating of these phases will offer important insights that have otherwise had to be inferred as to the process(es) of clastic diagenesis. Imagine the potential for understanding the geologic processes a rock has experienced if, in addition to temperature and salinity, one could also date the generations of cements that are recognized in a paragenetic study. This is a frontier in the Earth Sciences.

The major difference between clastic and chemical sedimentary rocks is that the initial constituents for clastic rocks have an inherited history, while newly formed chemical constituents in chemical sedimentary rocks, if unaltered, will give the age of deposition if they have high enough U/Pb ratios to be dated. After deposition, these chemical constituents also experience diagenesis to eventually become a rock, with unstable phases dissolving or being replaced and various cement phases and crosscutting veins influencing the U–Pb system in a similar manner as we discussed for clastic sedimentary rocks in the preceding paragraph. That is to say, in order to become a rock, we can imagine that all sediments have experienced multiple diagenetic realms with fluids that have different U/Pb which may dissolve some phases and precipitate others perhaps further down the path of fluid-rock interaction. These changes will alter the U–Pb systematics making it impossible to obtain a meaningful age through whole-rock analyses. However, if individual phases can be sampled, and this is increasingly being used particularly in carbonate rocks, a meaningful age of the new phases may be obtained which will allow geologists to date the timing of that event, not the rock.

Through geologic time, a rock is likely to have been exposed to multiple diagenetic fluids resulting in dissolution and precipitation of various minerals as well as solid-state exchange with others and thus producing a complex array of isotope and element ratios. It is in this framework that diagenesis of U–Pb must be considered. Sampling for U–Pb dating should target phases that can be recognized petrographically and can be put in a paragenetic framework. In this way, the system becomes even more powerful with the potential not only to date the time of deposition but also to date diagenetic events that postdate deposition.

Uranium-Lead, Zircon

Fernando Corfu*

Department of Geosciences, University of Oslo, Oslo, Blindern, Norway

Definition

Uranium-lead: Long-lived radioactive isotopes of uranium (^{235}U and ^{238}U) decay to stable lead (^{207}Pb and ^{206}Pb , respectively) at a rate, which is constant but different for the two systems. The ratio of accumulated lead to remaining uranium is a function of time and is a direct measure of the time of formation of minerals and rocks.

Zircon: A mineral consisting principally of zirconium, silicon, and oxygen and with trace amounts of uranium.

Main Characteristics of Zircon

Zircon is an orthosilicate with a tetragonal crystal structure and the chemical formula ZrSiO_4 . It occurs as euhedral to prismatic crystals of various elongations but also as grains with subrounded anhedral shapes due to resorption and grinding during metamorphic and/or sedimentary reworking (see Fig. 1). The mineral has a hardness of 7.5 and a density of 4.7 g/cm^3 , decreasing to 3.9 in heavily radiation-damaged (metamict) grains. Uranium is incorporated in the crystal in trace amounts (zero to several thousand parts per million) by replacing zirconium, which has a similar ionic radius and equal valence (+4). Other important trace elements are hafnium (1 %), thorium, yttrium, phosphorus, and the heavy rare earth elements.

Behavior of Zircon During High-Temperature Geological Processes

Zircon grown in slowly crystallizing magma chambers commonly exhibits regular growth zoning defined by alternating layers of slightly different chemical composition (see Fig. 2). This regular layering can be disrupted and modified by recrystallization processes leading to very complex internal textures. Zircon can survive partial melting processes and remain as a core, entrained from the source of the magma, inside new magmatic crystals. Protracted high-temperature metamorphic processes can recrystallize zircon expelling part of the accumulated lead. This process can be accompanied by growth of new layers of metamorphic zircon.

*Email: fernando.corfu@geo.uio.no

Fig. 1 Typical morphologies and other properties of zircon in common rocks. (a–c) Euhedral, colorless zircon with variable degrees of elongation; (d) euhedral zircon, prismatic and flat, locally turbid and fractured; (e) short-prismatic euhedral zircon with clear outer zones enclosing a cloudy, opaque core; (f) subrounded zircon of metamorphic origin with inclusions of coeval rutile. The grains are approximately 100–300 μm in size

Role of Zircon for U–Pb Dating

Zircon is the mineral most widely used for determining geological ages with the U–Pb system. The main reasons are (1) the incorporation of variable amounts of uranium, but essentially no lead, at the time of formation, so that virtually all the lead found in a grain of zircon today stems from the radioactive decay of uranium; (2) the very widespread occurrence of zircon in many different rock types; and (3) the resistance of zircon during weathering processes, metamorphic transformations, and melting of the host rocks (Hanchar and Hoskins 2003).

A further advantage for dating stems from the existence of two decay series in the uranium-lead systems. These two series run at different speeds, yielding two ages for the same dated object. If the two ages are equal, they prove that the mineral has remained a closed system and did not lose or gain Pb or U since the time of formation. If the two ages do not match, the system must have been open at some point, and the apparent ages have no immediate geological meaning.

Zircon requires no, or just marginal, corrections for initial lead, avoiding therefore a major source of uncertainty. For this reason, it is possible to achieve much higher precision for zircon than for most other uranium-bearing minerals. Modern isotope dilution thermal ionization mass

Fig. 2 Cathodoluminescence images of sectioned and polished zircon crystals – *bright zones* have low uranium contents, whereas *dark areas* are richer in uranium. (a) Regular growth zoning, but with some local discontinuities indicating resorption episodes in a magma; (b) zircon with sector zoning – a common appearance of zircon grown under high-temperature metamorphic conditions; (c) zircon crystal with very well-developed growth zoning, except for an internal zone with an irregular overprint indicating resorption and recrystallization; (d) interior of zircon with regular growth zoning surrounded by a broad rim of more uniform composition; (e) zircon crystal with internal convolute zoning; (f) zircon crystal with multiple growth zones – the internal part of a xenocrystic core is richer in uranium than the rims, its decay and volume expansion leading to fracturing of the surrounding layers; (g) zircon with regular growth zoning superimposed by a later crack-seal texture (Images courtesy of Sven Dahlgren, Alfred Kröner, and Kosuke Ueda)

spectrometry (ID-TIMS) can achieve precisions on the ages of better than 1% and resolve the timing of very complex geological processes (e.g., Schaltegger et al. 2009; Schoene et al. 2010; Wotzlaw et al. 2012).

The onlapping of multiple zones, reflecting growth or reworking at different times during the history of a zircon population, provides the opportunity to use composite grains or composite zircon populations to date such multiple events (e.g., Harley et al. 2007). Complex zoning, however, can also make the dating process very difficult in those cases where analysis represents mixed ages, possibly further complicated by superimposed lead loss effects.

Most applications of this method are oriented toward the determination of the time of magmatic or metamorphic crystallization of rocks, but zircon can also be used to study provenance of

Fig. 3 Detail of a zircon section showing regular growth zones that have become metamict with time. Those with more uranium (showing *low luminescence*) have expanded and fractured the zones with less uranium, less metamict (*brighter luminescence*), and more brittle. Fluids intruding along the fractures have developed alteration haloes (*alt*) that propagate into and change the metamict material (A full description is given in Nasdala et al. 2010; photograph courtesy of Lutz Nasdala, University of Vienna)

sedimentary rocks and constrain their time of deposition, or it serves to correlate strata linked to meteorite impact events (e.g., Kamo et al. 2011).

Effect of Radioactivity on the Structure and Behavior of Zircon

For each series, the radioactive decay of uranium (and thorium) emits 6–8 alpha particles, each accompanied by a recoil of the nucleus. This process destroys few nanometers of the crystal lattice of zircon around the decay sites. With time, the accumulation of radiation damage leads to an increase in the volume and a reduction of the density of the zircon, together with other physical and optical changes. Because zircon commonly consists of concentric zones with alternating, variable uranium contents, the expansion of uranium-rich zones stresses and eventually fractures the uranium-poor, and still crystalline, layers. The fractures create pathways along which fluids can penetrate in the crystal and cause chemical changes, including the removal of lead (see Fig. 3). Because the remaining uranium still resides in healthy lattice sites, loss of uranium is less likely than loss of lead.

Newly formed zircon crystals are colorless and transparent. With the increasing accumulation of radiation damage, which is proportional to U content and age, the zircon becomes gradually more colored, first pink, then red or brown and translucent, and eventually dark or white and opaque, the latter especially in chemically altered domains.

Strategies to Counter the Effects of Radiation Damage When Dating Zircon

In order to obtain geologically valid ages, it is important to avoid or minimize the use of zircon grains that have lost lead. This can be achieved first by selecting grains, or parts of grains, which are free of fractures and turbid domains. Zircon analyzed by isotope dilution thermal ionization mass spectrometry (ID-TIMS) can be initially treated by air and/or chemical abrasion. In the air abrasion treatment (Krogh 1982), the grains spin around inside a steel chamber by means of a jet of compressed air abrading away the outside layers, breaking fractured grains, and polishing them to remove the most radiation-damaged and radiation-altered parts of the grains and reduce the extent of lead loss. Chemical abrasion (Mattinson 2005) involves two stages. In the first stage, the grains are heated to 900–1,000 °C, annealing the parts of the zircon with a low amount of radiation damage, but not the most heavily damaged domains. In the second stage, the grains are immersed in hydrofluoric acid at 180–200 °C for 10–20 h, dissolving the most radiation-damaged parts of the grains but not affecting uranium and lead in the remaining crystalline parts of the zircon.

Zircon analyzed by ion probe or laser ablation inductively coupled plasma mass spectrometry is normally sectioned and polished and then examined using cathodoluminescence or backscatter electrons in order to identify optimal target areas (with diameters between 10 and 60 µm), which are free of alteration, fractures, or inclusions and suitable for uranium-lead analysis.

Because of the existence of the two parallel decay chains ^{238}U to ^{206}Pb and ^{235}U to ^{207}Pb , it is generally possible to recognize biased data reflecting the analysis of isotopically disturbed zircon (“discordant” data) and to extrapolate data for cogenetic zircon affected by variable amounts of lead loss to the “true” age of formation of the system.

Summary

The mineral zircon is an efficient geochronometer because of its widespread occurrence, resistance to destruction and isotopic resetting during magmatic or metamorphic events, incorporation of uranium but no initial lead at the time of formation, and its combination with the two chains of ^{238}U and ^{235}U , which operate at different rates while decaying to ^{206}Pb and ^{207}Pb , respectively. The main difficulty in dating zircon is related to the gradual accumulation of radiation damage, which destroys the zircon lattice, causes fracturing, and permits access to fluids, which leach out lead and bias the ages. Some of the most essential tasks involved in zircon dating are the identification of multiple generations of zircon in a population and the ability to isolate and analyze separately domains that have escaped loss of lead.

Definition

Dating of events associated with volcanism that leaves a permanent marker in tree-ring records. Such events include air temperature cooling, deposition of ash layers, lava flows, and magmatic degassing.

Introduction

The geological applications of dendrochronology cover a wide range of topics, from paleoseismology (Jacoby 1997) to paleovolcanism and its effects on climate (Zielinski 2000). With specific regard to volcanic eruptions, tree-ring records have been used in multiple ways to date events associated with explosive and effusive volcanism, including magmatic degassing. Because wood formation is influenced by environmental factors (Plomion et al. 2001), tree species that are directly or indirectly impacted by volcanic eruptions can record such events in their growth layers. Datable volcanic effects on woody species range from annihilation (death dates) to rebirth (establishment dates) but also include growth changes in surviving trees (Yamaguchi 1993). Such changes can be abrupt, hence only detectable in single rings. These individual growth layers can be very small (“microrings”), down to the point of not being present (“locally absent rings”) in one or more samples collected at a site (Biondi et al. 2003). Individual tree rings that are typically not so small can show anatomical damage from freezing (“frost rings”) in response to the sudden reduction of sunlight and its associated air temperature drop, caused by volcanic dust veils (LaMarche and Hirschboeck 1984). Depending on the type of extrusive materials (tephra deposition, lava flows, emission of sulfuric gases, etc.), surviving trees can present gradual, rather than abrupt, changes over multiple consecutive years. Such departures from previous tree-ring patterns can be positive (increased growth, or “release”) or negative (decreased growth, or “suppression”). The diversity of volcanic effects on trees depends on the variety of materials that can be ejected, as well as on the location, species, size, and age of the trees, together with other site conditions, from elevation and topography to vegetation features. On one hand, such richness of potential information has generated a long tradition of tree-ring applications to volcanology. On the other hand, the difficult task of identifying what, when, and how trees were impacted by specific past volcanic events has caused multiple, heated, and prolonged scientific debates.

Historical Development

Modern dendrochronology, which is the study of past changes recorded by wood growth, is based on the rigorous application of Crossdating techniques to assign calendar dates to tree rings (Fritts and Swetnam 1989). When so defined, this branch of science was established in the western United States at the beginning of the twentieth century by Andrew E. Douglass, an astronomer at the University of Arizona in Tucson (Webb 1983; Nash 1999). Tree-ring dating is closely connected with the study of wood formation, and relevant studies, for example, on the anatomy of frost rings (Rhoads 1923), also date back about a century. On the other hand, while the hypothesis that exceptionally cold years could be caused by volcanic eruptions is found in Benjamin Franklin's (1785) writings, the global atmospheric radiative effects of volcanic aerosols could only be tested with the advent of satellite and remote sensing technology in the 1980s (Ramanathan 1988). At about the same time, the Volcanic Explosivity Index, or VEI (Newhall and Self 1982), was introduced to describe the magnitude of past explosive eruptions in a semiquantitative manner. Impacts of extrusive eruptions on tree rings at sites located near a volcano were first described in the 1960s, but sample sizes were small (i.e., less than ten trees), ring boundaries were uncertain either because of poor sample preservation and surfacing (Druce 1966) or because of species growth patterns and anatomical features (Eggler 1967), and no crossdating was used. A notable exception was the A.D. 1064–1065 dating of Sunset Crater, Arizona (Smiley 1958), where a larger number of samples from archaeological ruins were investigated and tree-ring dates were assigned by crossdating. On the other hand, less than ten trees showed a distinct growth reduction after 1064, and nonvolcanic disturbances can cause similar effects in ring widths of the same species in this geographical area (Sheppard et al. 2005).

A major catalyst for dendro-volcanology came from the 1980 eruption of Mount St. Helens in the Pacific Northwest region of the USA. The blast that occurred on May 18 of that year with an estimated VEI of 5 (the maximum is 8) removed the top 400 m of the mountain and rose to 24 km into the stratosphere (Brantley and Myers 2000). It was the deadliest and most economically devastating volcanic event in United States history, exceeding a billion dollars in damage. A total of about 60 people, including a volcanologist, and more than nine million cubic meters of valuable timber were among the losses suffered over the nearly 600 km² ravaged by the eruption (McLean and Lockridge 2000). Several studies were published shortly thereafter on tree growth responses to the eruption (Mahler and Fosberg 1983; Hinckley et al. 1984) and on dendrochronological dating of previous events (Yamaguchi 1983, 1985). The enhanced interest in past volcanic histories, and the realization of potential long-range temperature effects from volcanic dust veils, prompted an extensive study of frost rings in the wood of high-elevation bristlecone pines (LaMarche and Hirschboeck 1984). Another anatomical feature, i.e., the “light rings” caused by reduced latewood formation in conifers growing at high elevations or latitudes, was investigated for their potential connection with reduced temperatures associated with volcanic eruptions (Filion et al. 1986). Extensive networks of tree-ring sites, whose analysis was then facilitated by advances in computational power and numerical processing, became the target of sophisticated statistical methods to detect changes in tree-ring-reconstructed climatic variables that could be linked to volcanic eruptions (Lough and Fritts 1987).

Yet another method of tree-ring analysis, X-ray densitometry (Polge 1970) had come of age in those decades (Schweingruber et al. 1978), and networks of tree-ring sites sampled in the late 1970s and early 1980s were analyzed using this new technique (Schweingruber et al. 1991). Subsequent research to date has continued to employ the tools elaborated in previous years, from light rings (Szeicz 1996) to densitometry (Jones et al. 1995), expanding the number of sampled sites (D'Arrigo

and Jacoby 1999) as well as the geographical (Hantemirov et al. 2004) or temporal (Salzer and Hughes 2007) range of previous studies, and applying increasingly complex numerical treatments for identifying volcanic signals in tree-ring proxy records (Breitenmoser et al. 2012). As an alternative to the exhaustive filtering and massaging of large spatiotemporal datasets, other studies in the past few decades have investigated the use of chemical markers in tree rings linked to volcanic eruptions (Pearson et al. 2009), including magmatic degassing in the absence of explosive events (Biondi and Fessenden 1999).

Basic Principles and Applications

Trees and other woody plants grow by covering themselves with a new layer of tissue every year (Larson 1994). When seen on a transverse section, such wood layers appear as concentric tree rings. Because tree growth is influenced by the environment, tree rings are then natural archives of past environmental conditions. For instance, less wood is formed near the base of a tree stem when climate conditions are less favorable, producing narrower rings (Speer 2010). If an eruption takes place, trees growing close enough to the volcano can be scorched by hot gases or covered with tephra and may either be killed or survive depending on their species, age and vigor, microsite conditions, as well as the chemistry and temperature of the gases and the thickness and coarseness of the tephra layer (Segura et al. 1994). Surviving trees typically experience abrupt suppression of radial growth (Hinckley et al. 1984), including locally absent rings (Yamaguchi and Hoblitt 1995). This immediate decline can be followed by a prolonged period of reduced radial increment (Segura et al. 1995) or by its opposite, i.e., greater than normal growth rates, often in connection with concurrent stand dynamics and resulting competitive interactions (Abrams et al. 1999).

Major explosive volcanic eruptions that inject dust and aerosols into the stratosphere are capable of causing large-scale surface cooling (Minnis et al. 1993). Distant, large-scale networks of tree-ring chronologies from temperature-limited sites can reflect those eruptions in anatomical xylem features, such as frost damage (D'Arrigo et al. 2001) or reduced latewood formation (Jacoby et al. 1999). Freezing damage to coniferous species causes the formation of deformed and collapsed xylem cells depending on the intensity of the frost, the degree of cambial activity at the time of the temperature drop, the tree species and size, and possibly other factors (Day and Peace 1934). Frost rings have been reproduced experimentally (Glerum and Farrar 1966), and their cross-sectional features are clearly distinguishable on a well-prepared wood sample at the magnification (10–50×) normally used in tree-ring studies. While crossdating among a large enough number of samples guarantees accurate dates, the year assigned to a frost ring may have some uncertainty if the injury occurs at a ring boundary, so that it could represent either a late frost in a year or an early frost in the following year. This situation is more frequent as ring widths become smaller (<0.1 mm), but using well-dated frost rings to resolve uncertain cases leads to potential bias and should be either avoided or well documented. With regard to “light rings”, the reduced cell wall thickening in latewood that causes their name also causes minimal density and can be caused either by low air temperature or by insect defoliation (Liang et al. 1997).

Measured annual growth parameters, such as ring width (Fritts 1976) or maximum latewood density (Briffa et al. 1988), are routinely used for dendroclimatic reconstructions. When wood formation is limited by air temperature, as it is usually the case for trees located at high elevations or high latitudes (D'Arrigo et al. 2006), dendrochronological parameters can reflect a volcanic cooling, thereby providing a record of past eruptions (Briffa et al. 1998). Chronologies developed from ring widths present a greater amount of time-series autocorrelation (or “persistence”) than chronologies

generated from annual density peaks (called maximum latewood density, or MLD), which also tend to reflect growing season conditions rather than integrating environmental signals over multiple years (D'Arrigo et al. 1992). Therefore, it is normally assumed that the temporal lag between volcanic cooling and its incorporation in tree-ring proxy records increases going from frost rings to light rings and from maximum latewood density to ring width chronologies (D'Arrigo and Jacoby 1999).

The main application of dendrochronology to volcanology is the definition of impacts on ecosystems and on human societies, either current, past, or long lost. Besides providing information on ecological processes in forests, tree-ring records of volcanic eruptions contribute to estimating the past frequency of destructive events. This numerical datum can then improve the definition of potential risks, especially with regard to explosive phenomena occurring at short intervals from one another (Yamaguchi 1985). At the same time, because of possible global impacts of volcanoes on climate (Robock and Mao 1995) and biogeochemical cycles (Krakauer and Randerson 2003), well-dated records of past eruptions are needed to improve the accuracy of models used to generate future scenarios linked to anthropogenic emissions of greenhouse gases (Ramanathan 1988). As any other dating tool, tree-ring records of volcanic eruptions can alter historical interpretations simply by changing the order of events. While dates are not by themselves reason for cause-and-effect relationships, they are able to negate theoretical ones as no effect can precede its hypothesized cause.

Current Controversies and Knowledge Gaps

Major volcanic eruptions have been dated using other types of records, from dust layers and chemical properties in ice cores (Larsen et al. 2008) to archaeological and written sources (Stothers 1999). Not all records agree, and in particular, dates assigned to some major eruptions using geochemical markers in Greenland ice cores (Vinther et al. 2006) are currently in disagreement with tree-ring records (Baillie 2010). A particularly important event is the Minoan eruption of Thera, an island in the Aegean Sea now called Santorini, which took place in the mid-second century BC. The date of this volcanic time marker is of critical importance for the stratigraphic and archaeological synchronization of ancient Eastern Mediterranean societies, the cradle of western culture. The eruption, which left a caldera and ash deposits up to hundreds of meters in size, has been linked with the collapse of the Minoan civilization on the island of Crete, 110 km to the south, possibly spurred by gigantic tsunamis. The controversy has lasted for decades, with historical/archaeological dates centered in 1550–1500 BC (Wiener 2009), tree-ring records pointing to 1629–1627 BC (Baillie 2010), ice-core geochemistry focused on 1642–1641 BC (Vinther et al. 2006), and radiocarbon dates spread over 1683–1611 BC (Manning et al. 2006). Each of these sources of evidence has strengths and weaknesses. As an example, radiocarbon dating of an olive branch from the eruption site provided a date range of 1627–1600 BC (Friedrich et al. 2006), but it is difficult to determine if the sample was dead or alive at the time of the eruption (Wiener 2010), and wood anatomical features make any ring analysis problematic for this species (Cherubini et al. 2013).

The chemical signature of volcanic eruptions has been proposed as a possible tool for testing the accuracy of tree-ring dates assigned to individual events (Pearson et al. 2005). Because elemental concentrations can vary considerably in the same tree both around the stem and at various heights in the trunk (Watt et al. 2007), clear evidence needs to be presented that specific chemical signals are replicable across samples from the same tree as well as from different trees of the same species and site (Kirchner et al. 2008). When crossdated ring sequences are combined with localized information on geochemical variables, a high degree of accuracy and confidence can be placed in the dating

(Sheppard et al. 2008). This, for instance, was the case with regard to the onset of magmatic degassing in forest stands of the Sierra Nevada, which produced abrupt changes in crossdated ring-width sequences (Biondi and Fessenden 1999) and in their radiocarbon concentrations (Cook et al. 2001).

A number of confounding factors hamper the use of proxy records for dating volcanic eruptions. Several of these factors can be categorized as false positives or false negatives (Cleland 2002). Considering anatomical markers in tree rings, not all of them are related to major volcanic eruptions (false positives), and known major volcanic eruptions took place without producing such markers (false negatives). In addition, not all cold summers over a region are related to volcanic events, and not all volcanic years produce a cold summer at the majority of sampled sites in a tree-ring network (D'Arrigo et al. 2013). Depending on the prevailing climate regime and ecological requirements of a species, climate-driven responses to major eruptions can even favor tree growth rather than depressing it. Such inverse response was proposed for Thera because the potentially cooler summers generated by the dust veil would have reduced evapotranspiration, resulting in 2–3 years of abnormally high growth in woody species adapted to the normally dry Mediterranean conditions (Kuniholm et al. 1996). These hypothetical responses, albeit reasonable, require further testing, which is best attained using detailed ecophysiological and anatomical studies at sub-monthly time scales (e.g., Rossi et al. 2013). Finally, when evaluating unusual episodes within a time series, it is best to employ a quantitative approach, such as ranking episode features (duration, magnitude, peak) according to predefined numerical criteria (e.g., Biondi et al. 2008).

An additional wrinkle in the protracted debate over tree-ring reconstructions of volcanic eruptions has recently emerged. Climate modelers have tried to reconcile their simulations of regional and global climate impacts from volcanic eruptions by postulating that tree-ring chronologies for northern latitudes or from high elevations are all consistently missing, and in more than one occasion, a year of growth (Mann et al. 2012). The ensuing vigorous responses (Anchukaitis et al. 2012; D'Arrigo et al. 2013; Esper et al. 2013) have concentrated on choices made when modeling tree-ring formation and on correlations with instrumental or proxy records, showing a general disruption of these statistical relationships when tree-ring chronologies are shifted by one or more years. The essential question underlying the debate is the likelihood that collections of tree-ring samples from a single site, or even from multiple sites in a region, would fail to include a year's growth. The frequency of locally absent rings increases in semiarid environments as a response to drought, but existing tree-ring collections pooled by latitude, species, or elevation include a percentage of "missing" rings that does not exceed 10 % (St. George et al. 2013). A number of other issues have been raised, starting from how evidence deteriorates going further and further back into the past. For relatively recent events, such as the 1815 explosion of the Tambora volcano (Stothers 1984), there is no chance of a universally missing ring given the large number of available proxy and instrumental records. For earlier eruptions, on the other hand, even their dates become less reliable as temporal separation increases (Plummer et al. 2012).

Historical archives and environmental records of past events are notoriously open to multiple interpretations, but so are model outputs and their underlying assumptions. From a tree-ring perspective, not all is known about the environmental conditions required for, and the biological mechanisms leading to, wood formation in areas where long proxy dendroclimatic records have been developed. Anatomical and ecophysiological studies have the potential to uncover such mechanisms without complex numerical analyses (Fonti et al. 2010; Rossi et al. 2012). On the other hand, the impossibility of experimental testing on past events (Biondi 2013), when combined with lack of self-criticism or doubt, could maintain the striking tendency to robust bragging that has become a distinguishing trait of high-profile articles on volcano-climate-proxy records connections.

Summary

Dendrochronological studies of volcanic eruptions employ a variety of techniques, from anatomical to statistical, for detecting the signals left by past events in tree-ring records. When large datasets composed of multiple sites and species are independently analyzed, the resulting tree-ring dates assigned to past events are more reliable than those derived from other proxy records or from modeling exercises. Dendrochronological dates are exact when sufficient sample replication exists, but the correct interpretation of environmental signals, including volcanic ones, that are embedded in wood anatomical markers and growth patterns requires careful consideration of alternative, competing hypotheses.

Luminescence, Glacial Sediments

Geoffrey A.T. Duller*

Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, Wales, UK

Definition

Glacial	Of, or pertaining to, ice masses of sufficient magnitude that they are able to deform under their own mass.
Glacial sediments	Detrital lithic materials deposited as a result either of direct glacial movement, such as a diamict, or an indirect consequence of glacial processes, such as fluvioglacial sediments.
Luminescence dating	The use of the luminescence signal emitted from a mineral for dating. For geological sediments, the event being dated is the last exposure to daylight, and this normally corresponds with deposition of the sediment.

Introduction

Luminescence dating of sediments associated with former glacial activity has been undertaken for over 40 years. Some of the earliest work undertaken on the application of luminescence to dating geological sediments was carried out in the former Soviet Union and included analysis of sediments resulting from a variety of different glacial processes. This work was not widely known outside the Soviet Union (see “► [Luminescence Dating, History](#)”), and in later reviews (e.g., Dreimanis et al. 1978; Wintle and Huntley 1982), it was criticized for some important errors.

A major challenge that has been common to all luminescence studies of glacially derived sediments is assessing whether they were exposed to sufficient light at deposition to reset the signal used for dating. Early work used thermoluminescence (TL) signals, and a great deal of effort was expended trying to assess what proportion of the TL signal remained at deposition so that ages could be calculated. Optically stimulated luminescence signals (OSL) tend to be reset by exposure to daylight more rapidly than TL, and when these methods became available, they were rapidly adopted for analysis of glacial sediments.

There are many different types of glacially derived sediments, and the likelihood of exposure to daylight prior to deposition varies considerably. It is clear that selection of depositional facies where exposure to daylight at deposition is most likely is important. The most suitable environments are probably those involving fluvioglacial or fluviolacustrine processes, though in both cases shallow water facies are much preferable to deepwater ones.

For some glacial sediments, OSL methods can be applied in a relatively straightforward manner, while in environments where the exposure to daylight is more limited, complex methods involving measurement of single grains are required in order to be able to identify the small proportion of grains within the sample that did receive sufficient daylight exposure to reset their signal and hence

*Email: ggd@aber.ac.uk

give an accurate age. Recent reviews of the application of OSL methods to glacially related sediments are provided by Fuchs and Owen (2008) and Thrasher et al. (2009).

History

The limited exposure of many types of glacially derived sediments to daylight was realized in early studies that studied the thermoluminescence (TL) signals. A great deal of work was undertaken to try to define the extent to which these TL signals were reset. Gemmell (1988) studied the change in the TL signal of suspended sediment collected along a 4 km long reach of a channel draining the base of the Austerdalsbreen glacier in Norway. Although he could observe that the TL signal decreased with distance downstream of the glacier, this decrease was irregular because of the incorporation of older material from the banks of the channel. Forman (1988) chose to study a range of different depositional environments around glaciers in Spitsbergen and found that tills and ice-proximal glaciomarine sediments appeared to have been exposed to light the least, while littoral and ice-distal marine sediments had been exposed for the longest. These studies of proximal glacial sediments implied that it was not possible to obtain accurate luminescence ages using TL methods.

Optically stimulated methods, both using visible (optically stimulated luminescence, OSL) and infrared stimulation (infrared stimulated luminescence, IRSL), were introduced in the 1980s and 1990s. They measure signals that are reset more rapidly by exposure to daylight than TL and thus may be more suitable for dating glacial sediments where exposure to daylight at deposition is limited. A second important innovation at this time was the development of single aliquot methods which made it possible to measure equivalent dose (D_E) using a single subsample (called an aliquot) and made it practical to make replicate measurements. Duller et al. (1995) was one of the first to use single aliquot IRSL measurements in glacial environments and analyzed a variety of glacially derived sediments from Scotland. Some of these sites had independent age control, and these showed that while some ages were consistent with the other geochronological methods, others were clearly inconsistent. This was progress over the use of TL methods, but major hurdles still existed. The methods available for analysis of the D_E estimates was crude at that stage, and the measurements of IRSL made at that time were prone to anomalous fading (see “► [Feldspar, Infrared Stimulated Luminescence](#)”).

Development of the single aliquot regenerative dose (SAR) method for OSL measurement of quartz, and improved understanding of the causes of variations in D_E between different aliquots, led to renewed efforts to apply luminescence to glacial sediments. Of particular importance was the development of statistical models such as the minimum age model (see “► [Luminescence Dating, Single Grain Dose Distribution](#)”) which can be used to identify within a set of replicate D_E measurements the population of aliquots which were best bleached at deposition. The development of instruments that were able to make measurements of the OSL signal from single grains (see “► [Luminescence Dating](#)”) was also important for some studies as changing the number of grains in an aliquot can be valuable in ensuring that the best bleached grains are seen (Olley et al. 1999). However, there is still debate within the academic community about whether measurements of single grains are more appropriate than using “small aliquots” where perhaps 10–30 grains are placed on each aliquot (Duller 2008). A common challenge when looking at the OSL signal from quartz isolated from glacial sediments is the low signal intensity, and this can make single grain measurements difficult.

The application of luminescence dating to glacial sediments can usefully be divided into those applications that have studied mountain glaciers and those that have studied sediments derived from large continental-scale ice sheets associated with Pleistocene expansions of ice cover.

Sediments from Mountain Glaciers

In the context of luminescence dating, the critical aspects of glaciers in mountainous terrains are that the transport distance between erosion and deposition of sedimentary material tends to be short, and the source geology is often dominated by intrusive igneous rocks. The impact of these characteristics is to give quartz whose OSL sensitivity is commonly very low. This means that the OSL signal emitted per unit of radiation (Gy) tends to be low and is often near the detection limit of available instruments. This has been a major challenge in areas as diverse as the Himalaya, Scotland, Chile, the Alps in Europe, and the Southern Alps in New Zealand (Preusser et al. 2006). Pietsch et al. (2008) measured the OSL sensitivity of quartz along a river course and showed that it increased downstream, presumably due to repeated cycles of erosion and burial. Such repeated transport cycles are unlikely in mountain glaciers.

These characteristics obviously do not apply to all mountain glaciers, but they are commonly observed. In some studies the quartz has had such low OSL sensitivity that it has not been possible to obtain ages (e.g., Lukas et al. 2007). In other areas it has been possible to obtain ages that are both geomorphologically consistent and which agree with Cosmogenic Nuclide Dating (Glasser et al. 2006). Many studies make measurements of aliquots containing many grains because of the low OSL sensitivity (e.g., Spencer and Owen 2004). Single grain measurements may be possible, though only a very limited proportion of grains may give sufficient OSL signal to be useful (~0.5 % of the grains in the samples from Chile studied by Duller (2006)).

Sediments from Continental-Scale Ice Sheets

In contrast to mountain glaciers, large continental-scale ice sheets typically have greater opportunities to incorporate material from a variety of geological sources, and detrital materials travel longer distances. The spatial scale of the sedimentary deposits also tends to be greater, and this may provide more opportunities for exposure to daylight. This is especially likely for glaciofluvial sediments and glaciolacustrine sediments. One of the largest bodies of work undertaken using luminescence dating was for the QUEEN project (Quaternary Environment of the Eurasian North; 1996–2002), where over 600 OSL ages were measured on quartz extracted from a wide range of sediments associated with former glaciation of the Russian arctic (Svendsen et al. 2004). Measurements on these samples generally showed that the OSL signal from quartz had been effectively reset at deposition (Thomas et al. 2006) presumably because of the long transport distances in such a large ice sheet. Furthermore, low OSL sensitivity is not reported to be a problem in this extensive study.

Conclusions

Luminescence dating of sediments associated with glacial activity is possible, provided that care is taken when sampling to choose facies with the greatest likelihood of exposure to daylight. Luminescence is often the only geochronological method that can be applied to glacial sediments. The

quartz OSL signal is generally the most appropriate signal for dating because it is reset by exposure to daylight so rapidly. However, in some areas the quartz OSL signal is very dim; this may be a challenge, and in extreme cases it may make it impossible to obtain an age. Replicate measurements of D_E , whether on small aliquots or single grains, are essential when studying glacially derived sediments because it provides a means of assessing whether the luminescence signal from the sample was effectively set to zero at deposition or not. Where there is evidence that not all the grains in a sample were reset at deposition, statistical methods such as the minimum age model (see “► [Luminescence Dating, Single Grain Dose Distribution](#)”) may be used to identify the population of grains that were bleached and hence enable accurate dating.

Bomb Carbon

George S. Burr*

NSF-Arizona Accelerator Mass Spectrometry Laboratory, University of Arizona, Tucson, AZ, USA

Synonyms

Bomb ^{14}C ; Bomb radiocarbon; Excess anthropogenic radiocarbon; Excess radiocarbon

Definition

Bomb carbon refers to anthropogenic radiocarbon produced and released into the atmosphere during aboveground nuclear weapons testing, primarily between 1945 and 1963.

Introduction

When Willard Libby introduced the radiocarbon method (Libby et al. 1949), global atmospheric radiocarbon (^{14}C) from nuclear weapons fallout was undetectable. This soon changed, however, as weapons testing programs accelerated during the 1950s and into the 1960s. At the same time, new radiocarbon laboratories were being established in Europe, North America, Africa, and Australia. It did not take long for researchers to discover a dramatic increase in atmospheric ^{14}C from nuclear weapons testing fallout, in both the Northern Hemisphere (de Vries 1958; Broecker and Walton 1959; Münnich and Vogel 1958) and the Southern Hemisphere (Rafter and Fergusson 1957; Münnich and Vogel 1958; Broecker and Walton 1959). This nuclear weapons-related radiocarbon became known as *bomb carbon*. The production of bomb carbon accelerated in the late 1950s and early 1960s as tests became more numerous and the explosive power of nuclear weapons increased dramatically. By 1963, the radiocarbon content of the atmosphere reached its peak when a nuclear test ban treaty put an end to aboveground nuclear weapons testing.

Plotted versus time, atmospheric bomb carbon follows a curve with a sharp increase in the 1950s and with a peak production in the early 1960s. Atmospheric bomb carbon peaks around 1964 and then declines rapidly (Fig. 1). This feature is often referred to as the radiocarbon *bomb pulse*, *bomb spike*, or *bomb curve*. The decline of atmospheric bomb carbon marks the end of aboveground nuclear weapons testing and illustrates the subsequent rapid removal of atmospheric $^{14}\text{CO}_2$ by the oceans (Craig 1957; Revelle and Suess 1957) and biosphere. The oceanic uptake of bomb carbon has been extensively documented by direct seawater analyses (Stuiver et al. 1981; Key et al. 2004), and biospheric uptake is reflected in tree-ring ^{14}C records. These examples represent two primary pathways of the carbon cycle – a global dynamic system that moves carbon within and between the atmosphere, oceans, biosphere, and lithosphere. They also illustrate the chief importance of bomb carbon to science, as an isotopic tracer and time marker.

^{14}C Production

Radiocarbon is produced naturally in the Earth's atmosphere, as cosmic rays collide with atmospheric molecules. These collisions result in a variety of particles, including secondary thermal neutrons. A portion of these thermal neutrons (n) interact with atmospheric ^{14}N and produce ^{14}C and protons (p) by the reaction:

This is the dominant pathway for the formation of natural radiocarbon on Earth (Libby 1955), and it is a consequence of the relatively large thermal neutron cross section (~ 1.8 barns) for the $^{14}\text{N}(\text{n}, \text{p})^{14}\text{C}$ reaction (Lal and Peters 1967). Aboveground nuclear weapons tests produce carbon in the same manner as cosmic rays because the atmosphere is rich in nitrogen and both fission- and fusion-based nuclear weapons provide an ample supply of thermal neutrons.

Estimates for the total amount of bomb carbon produced during the years of aboveground nuclear weapons testing are on the order of 10^{28} atoms. These values are usually expressed in multiples of 10^{26} ^{14}C atoms, or in kmol ^{14}C ($1 \text{ kmol } ^{14}\text{C} = 6.02 \times 10^{26}$ atoms). Since atmospheric carbon rapidly exchanges with carbon in the ocean and biosphere, it is not possible to directly measure the integral total production of bomb radiocarbon during the years of testing. An alternative is to estimate a value that sums the output from individual weapons tests. Naegler and Levin (2006) used this approach to estimate total production from 1945 to 1980 at $598\text{--}632 \times 10^{26}$ ^{14}C atoms, based in part on estimates from Enting (1982), Enting and Pearman (1982), Rath (1988), Hesshaimer et al. (1994), Lassey et al. (1996), and Yang et al. (2000). The amount of bomb carbon produced by a particular nuclear explosion is related to the amount of energy released. The precise yield, however, depends on factors such as the type and design of a given nuclear weapon, the altitude of the blast, and environmental conditions (Glasstone and Dolan 1977). These factors lead to intrinsic uncertainties in the calculation of the exact amount of total bomb carbon produced by weapons testing (Tans 1981; Naegler and Levin 2006), hence the broad range quoted above.

The natural production rate of ^{14}C in the atmosphere is currently about $2 \text{ atoms cm}^{-2} \text{ s}^{-1}$ (Castagnoli and Lal 1980). Multiplying this by the surface area of the Earth ($5.1 \times 10^{18} \text{ cm}^2$) and multiplying by 1 year ($3.15 \times 10^7 \text{ s}$) gives a ballpark average for the annual production of natural radiocarbon on Earth, which is 3.21×10^{26} atoms. A comparison with the estimate from Naegler and Levin (2006) implies that the total production of bomb carbon amounts to approximately 190 years of natural production.

Records of Atmospheric Bomb Carbon

Atmospheric records of bomb carbon are important to climate modelers because the bulk of ^{14}C produced by nuclear weapons was injected into the stratosphere. Stratospheric measurements of bomb carbon using aircraft and balloons have been compiled by Telegadas (1971). These data provide constraints on the total bomb carbon production estimates described above (Tans 1981; Naegler and Levin 2006). For the purpose of radiocarbon dating, it is the tropospheric radiocarbon values that are pertinent because the troposphere is in direct contact with the planetary boundary layer where plants and animals live.

Tropospheric records of bomb carbon are obtained from direct measurements of atmospheric CO_2 and from measurements of trees. Trees can be used to reconstruct radiocarbon time series because they incorporate carbon directly from the atmosphere (through photosynthesis) and because they form annual growth rings suitable for age control. Tans (1981) compiled a composite record of global atmospheric and marine bomb carbon using a variety of sources as a database for modelers. Levin and Kromer (2004) published a detailed atmospheric bomb carbon record from Europe, for the period 1953–2003, based on measurements of atmospheric CO_2 . Hua and Barbetti (2004) made a detailed comparison of atmospheric records from around the world. Their results showed a large difference between the two hemispheres, with the highest values in the Northern Hemisphere and lowest values in the Southern Hemisphere (Fig. 2). These differences are much greater than the well-

Fig. 2 Atmospheric radiocarbon from nuclear weapons testing in the 1950s and 1960s. Note the different amplitude and rate of increase in the Southern Hemisphere, as compared with the Northern Hemisphere. Zones represented in the figure are *NH1* Northern Hemisphere high-latitude sites, *NH2* and *NH3* Northern Hemisphere mid- to low-latitude sites, and *SH* Southern Hemisphere (Figure from Hua and Barbetti (2004))

known natural differences between the two hemispheres described by McCormac et al. (1998) and Hogg et al. (2002). Hua and Barbetti (2004) also documented bomb carbon zonation within the Northern Hemisphere and proposed four primary curves to describe the bomb pulse: NH1, NH2, NH3, and SH (Fig. 2). As shown below, these records are critical to a bomb carbon age determination because they represent the starting point of a sample for a particular region.

Records of Marine Bomb Carbon

The ocean is the world's largest carbon reservoir (Craig 1957; Revelle and Suess 1957), and characterizing the transfer of bomb carbon into the oceans and its subsequent transport within individual water masses became the subject of intense study following the era of aboveground nuclear weapons testing. The multinational Geochemical Ocean Sections Study (GEOSECS) formally began in 1967 and included a large number of scientific cruises across the Pacific and Atlantic Oceans (Craig 1972, 1974; Craig and Turekian 1976, 1980). A key element of the GEOSECS program was to study the distribution of ^{14}C in marine surface waters and at depth (Stuiver et al. 1981). A second such program, the World Ocean Circulation Experiment (WOCE), was conducted in the 1990s (Key et al. 2004). The WOCE program initiated the construction of a dedicated accelerator mass spectrometry (AMS) facility in Woods Hole, MA, which eventually produced over 13,000 radiocarbon measurements from seawater (McNichol et al. 2000). These and other programs were instituted to provide the type of three-dimensional data coverage and measurement precision necessary for climatological modeling. The records produced are also ideal for radiocarbon dating in the ocean.

A second significant source of marine bomb ^{14}C records comes from radiocarbon analyses of corals (Druffel and Linick 1978; Druffel 1981, 1987). Certain reef-building corals produce annual growth rings that allow for the determination of calendrical ages. When paired with radiocarbon measurements, corals offer an excellent archive for the reconstruction of radiocarbon time series, analogous to the terrestrial example of trees. Many thousands of such dates have now been published, and these feature much finer geographic and time resolution than seawater measurements collected during individual cruises.

Dating with Bomb Carbon

Dating with bomb carbon follows the same logic as traditional radiocarbon dating. A date is determined by comparison of the measured ^{14}C content of a sample with calibrated ^{14}C time series records. The sharp rise and fall of the bomb pulse makes it possible to date very accurately (within a few years) events which occurred since the late 1950s. The ^{14}C content of a sample can be measured using decay counting or by AMS. AMS results are usually expressed as fraction of modern carbon (F) values, defined as (Donahue et al. 1990)

$$F \equiv \frac{\left(^{14}\text{C}/^{13}\text{C} \right)_{\text{sample}[-25]}}{\left(^{14}\text{C}/^{13}\text{C} \right)_{1950[-25]}}, \quad (2)$$

Fig. 3 Sample calculation of a bomb carbon date. The fraction modern carbon value ($F = 1.6000$) is projected onto the atmospheric $^{14}\text{CO}_2$ data of Levin and Kromer (2004) along the dashed line. This gives two possible ages for the sample, at 1963 and 1967–1968. The width of the atmospheric curve includes two sigma uncertainties

where $(^{14}\text{C}/^{13}\text{C})_{\text{sample } [-25]}$ is the measured ratio of the sample, corrected to $\delta^{13}\text{C} = -25\text{‰}$, and $(^{14}\text{C}/^{13}\text{C})_{1950 [-25]}$ is the $\delta^{13}\text{C}$ -corrected ratio for the standard, adjusted for decay to the year 1950 (the “zero” year for radiocarbon dating).

Figure 3 shows an example of a radiocarbon age determination using bomb carbon for a sample with a fraction modern carbon value of $F = 1.6000 \pm 0.0050$. This example employs the atmospheric curve of Levin and Kromer (2004), appropriate for northern Europe. The age of the sample is determined by projecting the measured F value onto the bomb carbon curve. This gives two possible ages: (1) in 1963 and (2) 1967/1968. The uncertainties in this procedure can be obtained graphically or calculated. The CALIBOMB program, supported by Queen’s University Belfast, is freely available to calculate and plot bomb radiocarbon dating results using the Levin and Kromer (2004) dataset (www.calib.org).

Applications of Bomb Pulse Radiocarbon Dating

The application of bomb pulse radiocarbon dating cuts across many disciplines. The common feature of these studies is that they are concerned with events that transpired within the past 50 years. Recent examples from the literature include the following: (1) Fisheries Sciences, where bomb carbon dating has been used to determine the age of fishes as a critical component of population assessments (Andrews et al. 2011; Passerotti et al. 2010); (2) Forensic Sciences, where bomb carbon dating has assisted in the identification of crime victims (Speller et al. 2012) and to analyze the production to marketing cycle of the illicit drug trade (Ehleringer et al. 2012); (3) Earth Sciences, where bomb carbon has been used to determine the growth rate of cacti in reconstructing records of precipitation (English et al. 2010) and to determine the growth rate of speleothems (Hodge et al. 2011); and (4) Environmental Sciences, where bomb carbon has been used to determine rates of recent soil development and shoreline accretion (Lovelock et al. 2010). Applications of bomb pulse radiocarbon dating have expanded in recent years, and with radiocarbon’s

relatively long half-life ($\sim 5,700$ years), it is likely that this expansion will continue into the foreseeable future.

Summary

Aboveground nuclear weapons testing conducted between 1945 and 1963 nearly doubled the amount of ^{14}C in the atmosphere with the addition of bomb carbon. After the nuclear test ban treaty was signed in 1963, this excess atmospheric radiocarbon rapidly diminished through exchange with the oceans and biosphere. This rise and fall of atmospheric radiocarbon created a global radiocarbon bomb pulse that serves as a time marker for a wide range of dating applications.

Electron paramagnetic resonance (EPR) dating

Definition

Electron spin resonance (ESR) dating. Radiation exposure dating method using radiation-sensitive ESR signals, which operate like natural dosimeters. An ESR age calculation derives from the ratio of the accumulated dose (DE) of a sample to the background natural radioactivity within a range of 30 cm and cosmic doses.

Introduction

Electron spin resonance (ESR; sometimes called electron paramagnetic resonance, EPR) dating of corals has become an efficient tool in earth sciences for paleoenvironmental studies on coral reef terraces in the last 20 years. The first systematic studies and geochronological applications of ESR dating of corals started in the 1980s and early 1990s. They were carried out on sites with raised coral reef tracts in southern Japan (e.g., Ikeya and Ohmura 1983; Ikeya 1983), in Haiti (Skinner 1985), and in Barbados (Radtke and Grün 1988; Radtke et al. 1988; Grün et al. 1992). Since then, several methodological improvements and the development of more stable and high-resolution ESR spectrometers have significantly increased the quality of ESR dating results. The latter is strongly supported by the comparison of ESR dating results with radiocarbon (^{14}C) and TIMS $^{230}\text{Th}/^{234}\text{U}$ data (see below). By ESR dating of raised coral reef terraces, it is possible to distinguish between the major periods of high sea level during the last 500,000 years but also to differentiate between submaxima, for example, the submaxima MIS 5a-1 (c. 74 ka), MIS 5a-2 (c. 85 ka), MIS 5c (c. 105 ka), MIS 5e-1 (c. 118 ka), and MIS 5e-2,3 (ca. 128–132 ka), during the MIS 5 sea-level highstand (e.g., Schellmann et al. 2004; Schellmann and Radtke 2004a). However, an accurate differentiation between MIS 9, MIS 11, and older sea-level maxima is often limited by considerable alterations and recrystallization processes within these older coral samples. Also, the problem of natural “ESR rejuvenation,” which is the recombination of electrons that increases until a natural equilibrium is reached, must be addressed (e.g., Grün 1989; Rink 1997; Jonas 1997).

Physically, the upper dating limit of the ESR method is defined by this natural equilibrium limit. Despite this, weak weathering and slight recrystallization from a primary aragonite to a calcite

*Email: gerhard.schellmann@uni-bamberg.de

Fig. 1 Generalized principle of ESR dating of aragonitic coral.

coral fabric, which defines age rejuvenation effects, often cause a progressive underestimation of ESR ages before this upper dating limit is reached.

Methodology

The electron spin resonance (ESR) dating technique is one of several radiation exposure dating methods based on radiation dosimetry such as thermoluminescence (TL), optically stimulated luminescence (OSL), and radioluminescence (RL). All these methods use the phenomenon of common minerals, like the aragonite fabric of corals, acting as natural dosimeters. The radiation (natural radioactivity and cosmic rays) causes charges (electrons, free radicals) which are trapped at defects in the crystal lattice of a wide range of minerals. This naturally accumulated dose can be determined by ESR. The basic principles of the physics and the application of the ESR dating technique have been provided, for example, by Walther et al. (1992), Ikeya (1993), Rink (1997), Jonas (1997), Sharaf and Hassan (2004), Blackwell (2006), and Grün (2007). Schellmann et al. (2008) have reviewed the accuracy of ESR dating of corals, mollusk shells, and quartz. Blackwell et al. (2007) used coupled $^{230}\text{Th}/^{234}\text{U}$ and ESR coral dating for reconstructing sea-level changes since the last interglacial maximum (MIS 5e).

Here, we will focus on ESR dating aragonite coral samples. The time-dependent accumulations of trapped charges form paramagnetic centers, which can be detected by the rise of the ESR signal at $g = 2.0007$ (Fig. 1). Multiple scans (e.g., 5–40 scans) increase the precision of ESR signal amplitude measurements. The amount of trapped charge accumulation (paleodose, D_E) increases with time and can be quantified by ESR.

Fig. 2 Uranium content (ppm) of modern, Holocene, and Pleistocene corals (Details are provided in Schellmann et al. (2008)).

An ESR age is derived from the ratio of the accumulated radiation dose D_E (equivalent dose) to the natural radiation rate D' (dose rate) within a range of 30 cm, to which the sample was exposed in the past (Fig. 1). The D_E is determined by an additive dose method. For this method, more than 12 aliquots (Schellmann and Radtke 2001) of the same sample are stepwise irradiated with increasing artificial γ -doses (e.g., using a ^{60}Co gamma source). The growing amplitude of the ESR signal at $g = 2.0007$ of a coral sample is proportional to the number of trapped charges (D_E), which is dependent on the strength of natural irradiation (dose rate, D') and on the radiation time (=age of the sample). A living coral does not contain the ESR dating signal at $g = 2.0007$, which means the ESR intensity is zero. The D_E is determined by extrapolating the resulting dose-response curve to zero ESR intensity. In the case of dating corals or mollusk shells, the D_E – $D_{\max}$ plot procedure (D – DP procedure) should be used for the calculation of D_E (Fig. 1) as described by Schellmann and Radtke (2001).

The former natural dose rate (D') of a coral sample is estimated based on the content of uranium (U) (other radioactive elements like thorium and potassium are of no relevance) and the intensity of the cosmic dose rate (Prescott and Hutton 1994). Most colonial corals of sub-modern, Holocene, and Pleistocene corals have mean U contents of about 2.9–3.2 ppm (Fig. 2). This illustrates a prevailing U uptake of corals from seawater during their lifetime or shortly after death. Consequently, ESR ages of corals should be calculated using a recent or early U uptake model. However, some extremely high (up to 5 ppm) and low (below 2.5 ppm) U concentrations indicate significant U loss or gain; both limit a reliable age determination. But U-series dating results of corals are strongly influenced by U migrations than ESR. Therefore, the application of both methods can be valuable. For dose rate calculation, an alpha efficiency (k-factor) of 0.06 ± 0.02 should be used (Grün 2007). The correct determination of D' and D_E is essential for any ESR age estimation. The average error range when dating corals is between 5 % and 8 %.

Improvements in annual dose rate (D') estimation and the newly developed approach of equivalent dose (D_E) determination (D_E – $D_{\max}$ plot procedure) increase the precision of ESR dating Holocene and Pleistocene corals (Schellmann et al. 2008). This is strongly supported by comparing ESR dating results with other numeric dating methods such as radiocarbon (^{14}C) and TIMS U-series analysis (TIMS $^{230}\text{Th}/^{234}\text{U}$). Such correlations are published, e.g., by Radtke et al. (2003),

Fig. 3 ESR and TIMS Th/U ages of uplifted Middle and Late Pleistocene coral reef terraces in a transect on southern Barbados (Details are provided in Schellmann and Radtke (2004a, b)).

Schellmann et al. (2004, 2008), and Muhs et al. (2012). They are exemplarily illustrated in the following case study from Barbados.

Case Study: ESR Dating of Pleistocene Coral Reef Terraces

The elevated coral reef terraces on the Caribbean island of Barbados are a typical region for both the reconstruction of Late and Middle Pleistocene sea-level changes (classical “Barbados Model”) and, as one of the most common applications of ESR dating, the accuracy of ESR dating results on fossil corals up to c. 600 ka. Since early systematic studies by Radtke et al. (1988) and Radtke (1989), new geological, morphostratigraphic, and chronostratigraphic investigations during the past two decades led to several methodological improvements of ESR dating on coral and deliver some impressive examples of the application of this method (e.g., Schellmann and Radtke 2004a, b).

On southern Barbados, several uplifted Pleistocene coral reef terraces formed during oscillating MIS 5 and MIS 7 sea-level maxima are well preserved between the present coastline and the inland (Fig. 3). They rise up to 67 m above modern sea level (asl) and are accompanied to the center of southern Barbados by more elevated older Middle Pleistocene coral reefs formed during MIS 9 to MIS 11 sea-level highstands. Based on geological, morphostratigraphic, and chronostratigraphic methods, the uplifted MIS 5 and MIS 7 coral reefs of southern Barbados can be subdivided into up to seven clearly distinguishable main coral reef terraces (T1 to T7) and some less prominent

Fig. 4 ESR and TIMS Th/U ages ($\delta^{234}\text{U} > 141$ and $< 157\text{‰}$) of MIS 5a-1 coral reef terrace near Inch Marlowe Point, southern coast of Barbados (Modified after Schellmann and Radtke (2004a), and Schellmann et al. (2004)).

sublevels (e.g., T-6a and T-6b, T-1a₁ and T-1a₂). The youngest reef terraces are located at the lowest elevations close to the present coast, while older reef tracts have higher elevations and generally a greater distance from the coast. Due to the relatively slow uplift rate in southern Barbados (approx. 0.27 ± 0.02 m/1,000 a), the youngest Late Pleistocene coral reefs (T-1a₁) have been formed during MIS 5a-1 at approx. 74 ka (ESR) or 77 ka (TIMS Th/U) and the oldest and highest MIS 7 reef terrace (T-7) during a MIS 7 sea-level maximum approx. 224 ka (ESR). Both dating methods support in general a geochronological differentiation of the MIS 5a reefs into two sea-level submaxima (T-1a₁, T-1a₂) around 74 ka (ESR) or 77 ka (Th/U), and 85 ka (ESR) or 84 ka (Th/U). The three T1b, T2, and T3 coral reef terraces were formed during the MIS 5c around 104–105 ka (ESR) or 102–103 ka (Th/U). The three coral reef terraces (T4, T5a, T5b) are of MIS 5e age around c. 118 ka (ESR) or 120 ka (Th/U), and 132 ka (ESR) or 128 ka (Th/U) for the oldest MIS 5e reef terrace, respectively. However, an age differentiation of the three MIS 7 reef terraces (T6a, T6b, T7), which were formed around 200–224 ka (ESR), is still not possible. The correlation between age and height of the reef terraces allows to calculate neotectonic movements and to estimate paleo-sea-level changes (e.g., Schellmann et al. 2004; Radtke and Schellmann 2005).

The example shows that generally the timing of coral reef growth determined by both dating methods agrees well, especially when the error ranges are considered. However, ESR and TIMS Th/U age estimates from an MIS 5a-1 coral reef near the south point of Barbados (Fig. 4) illustrate that many ESR ages are up to 5–10 % younger than the corresponding U-series dates, respectively. The U-series data shows a slightly overestimation of the expected age. This data set illustrates very well that the apparently minor analytical errors (precision) of U-series data (less than 1 %, ESR between 5 % and 8 %) give no evidence of a better time resolution (Schellmann et al. 2004). The age estimates were carried out on paired samples. They show that the spread of individual ages (not considering errors) for both methods is about 4,000 year, although all ages were produced on individuals from the same branch of coral, which are hence most likely of the same age (grown within not more than a few hundred years). Therefore, age differentiations between single Late Pleistocene coral reef deposits that have developed in time periods of less than 4,000–5,000 years are little reliable, independent from the applied dating technique (ESR or TIMS U-series).

Summary and Conclusions

Due to methodological advances, which significantly increase the accuracy of ESR dating of Pleistocene and Holocene corals, ESR dating has become an efficient tool in earth sciences in the past two decades, especially for geochronological studies on coral reef terraces. ESR dating of Pleistocene corals permits to differentiate between the main Marine Isotope Stages (MIS) 5, 7, 9, 11, and 13 as well as between the substages 5e-2,3 and 5e-1, 5c, and 5a-2 and 5a-1. The average error is about 5–8 %. Late Pleistocene corals can be dated with a similar accuracy as with the TIMS U-series method in this time range, although the individual errors of ages are significantly larger than those of U-series data. The advantage of ESR, however, is that the upper dating limit for corals is probably above 500,000 year. If weathering and recrystallization from primary aragonite to calcite of the coral material could be excluded, dating of coral with an age of several million years should be feasible from the physical point of view. All in all, future research in ESR dating corals should be focused on the creation of a single-aliquot dating technique, which uses orientated aragonitic polycrystals.

Synonyms

Walther's law; Law of facies

Definition

The Walther's Law of Facies was introduced by the German geologist Johannes Walther (1860–1937) as an important geological principle, after the establishment of the concept of “facies,” one of the foundations of modern stratigraphy. Walther's Law states that any vertical progression of facies is the result of a succession of depositional environments that are laterally juxtaposed to each other.

The original definition (Walther 1894) reads as follows and was translated from the original German language by G. Middleton in 1973:

The various deposits of the same facies-area and similarly the sum of the rocks of different facies-areas are formed beside each other in space, though in a cross section we see them lying on top of each other. As with biotypes, it is a basic statement of far reaching significance that only those facies and facies-areas can be superimposed primarily which can be observed beside each other at the present time.

– Walther's Law of Correlation of Facies (1894)

Contextual Background

A “sedimentary facies” or simply “facies” is a term assigned to a sedimentary rock unit referring to its distinct and specific identifiable (i.e., descriptive) characteristics, produced by physical, biological, and/or chemical processes, during formation and from which an interpretation of its origin may be made (Middleton 1973; Reading 1996). Hence, a facies is generated during specific sedimentological conditions, reflecting a distinct depositional environment and associated processes. They can be single layers (few millimeters thick) or a series of thick beds (tens to hundreds of meters thick).

Sedimentary facies can be grouped spatially by associating genetically related lithologies that reflect linked environments in the stratigraphic record. This is known as a lateral association or assemblage of sedimentary facies (also called a facies tract) and is usually a lithofacies (rather than biofacies). Another type of association is the “facies sequence” which is a term assigned to distinct vertical stacking, succession, or sequence of facies that reflects a particular depositional environment or linked environments in the stratigraphic record (Middleton 1973).

Walther's Law simply states that both vertical and lateral facies match. A depositional system may contain several environments. Deltas contain channels, mouth bars, and prodelta muds, and consequently the sedimentary rock types (i.e., facies) in a depositional system may be variable, recording

*Email: lopezgi.phd@gmail.com

the specific characteristics of their component depositional conditions (e.g., sandy channels and mouth bars, muddy prodeltas). However, these environments can shift laterally causing sediment to stack vertically. As a depositional environment shifts, so too must the sedimentary facies in any one location change. As time progresses, the positions of facies also progress laterally in space and time; hence, the laterally related environments become superimposed forming vertical successions. This process results in deposition of time-transgressive sedimentary formations, in which the vertical stacking of facies records the originally laterally continuous environments (Reading 1996; Middleton 1973). Sedimentary environments that were once laying down side-by-side (facies tracts) will eventually end up overlapping one another over time, forming vertical facies successions, reflecting successive changes in the environment such as marine transgressions and regressions.

Facies associations (vertical and lateral) allow the study of sedimentary facies in space and time and their relationship with longer-term cycles, such as relative sea-level changes or tectonic phases, and subsequent accumulation in sedimentary basins (Friedman et al. 1992). The combination of both lateral facies tracts and vertical facies successions can be used to map broader three-dimensional depositional systems tracts that migrate through time and space as a function of cyclic forcing, such as eustasy. Identifying and mapping these depositional systems tracts and how they change through time are a fundamental component of Sequence Stratigraphy and an important strategy in the interpretation of the origin of sedimentary rocks and paleogeographic reconstructions (Friedman et al. 1992).

Geography, eustasy, isostasy, tectonism, and sediment supply are major controls on the relationships between stratigraphic facies. A classic example of the Law of Facies is the vertical stratigraphic sequence depicting marine transgressions and regressions.

Walther's Law of Facies is applicable only when the sedimentary sequence is continuous, with no hiatuses or breaks.

Dendrochronology, Progress

Laia Andreu-Hayles and Caroline Leland*

Tree-Ring Laboratory, Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA

Definition

Dendrochronology derives from the Greek words “dendron” (tree) and “chronology” (study of time), and it allows for the precise dating of annual tree rings based on the analysis of tree-ring patterns among several trees. Dendrochronology combined with other disciplines has allowed for substantial progress in environmental studies (see [Cross-References](#)).

Introduction

During recent years, dendrochronologists have faced the challenge of getting more information from tree rings, pushing its own limits to understand a wider range of climatic/environmental factors, to obtain seasonal resolution, and to reconstruct larger spatial scales and longer temporal time spans of climate variability. This is important because instrumental records cover only a limited time period and are insufficient for characterizing decadal and centennial climatic features. Different strategies are being explored to address these challenges. First, different standardization approaches have been designed to retain lower frequencies of climate variability, a frequent pitfall of traditional standardization methods used in tree-ring research. Low and medium frequencies allow us to assess long-term variations in climate and to determine the magnitude and range of climatic conditions through time. This information provides a context to investigate, for instance, whether the recent anthropogenic upward temperature trend is unusual compared to other persistent warm periods during the past, such as one occurring during Medieval Times. Second, several technological advances have allowed for measuring other tree-ring parameters in addition to the more classical methods (i.e., the width and the maximum density of the rings). Stable isotope analyses that include geochemistry and mass spectrometry, as well as wood anatomy analyses using high-resolution imaging, are becoming some of the most popular approaches in the search for different kinds of environmental information. These and other related topics are discussed in the sections below.

Standardization Methods

Tree-ring width series often consist of different components, such as age-size growth trends, environmental signals (e.g., climate variability), growth patterns due to disturbance, and noise. The objective of the study defines which component is considered signal or noise. Therefore, retaining the signal of interest (or removing the noise) in the tree-ring data determines the standardization

*Email: cleland@ldeo.columbia.edu

method to be chosen. **Standardization** is the process through which we convert individual tree-ring measurements into dimensionless indices to create a site chronology. This step is used to first make all the trees equally contribute to the mean of the site chronology and second to reduce or remove variability in tree-ring series that is not of interest for the overall research question. For instance, the removal of any nonclimatic variability in tree-ring measurements (e.g., age-size trend) is necessary to retain as much climatic information as possible, and it is one of the greatest challenges in dendroclimatology. Proper removal of nonclimatic trends might suggest that the resulting indices represent an ideally pure climatic signal. The concept of standardization is fairly simple in theory, but the practice has proven to be much more complex. Some new methods designed to preserve as much climatic information as possible are discussed in the following.

The traditional methods of standardization have been outlined and thoroughly discussed in several publications (e.g., Fritts 1976; Cook and Kairiukstis 1990). Perhaps the most basic of these methods is removal of the age-size growth trend through fitting deterministic sloping lines or negative exponential curves to the measurement series (Fritts 1976). However, several adaptations and improvements to this method have been applied within the last few decades, such as standardization methods for closed-canopy forests or trees with potential disturbance signals using stochastic (i.e., flexible) curves such as the cubic smoothing spline (Cook and Peters 1997; Cook 1985). Additionally, attempts have been made to reduce variance biases from the conventional “ratio” method of calculating tree-ring indices through the “residuals” method in conjunction with power transformation (Cook and Peters 1997; Helama et al. 2004). Please refer to an earlier version of the encyclopedia for more specific information on the classical standardization techniques (Buckley 2009). All standardization methods have their own advantages and disadvantages, and the method(s) used for a particular study must consider the trees and the environment in which they are located. However, as a common feature, all these traditional methods are based on data-adaptive curve-fitting approaches that limit the preservation of medium- and low-frequency variability. The extent of longer-term variability removed depends on the chosen detrending method, though the longest timescales are restricted by the “segment length curse” (Cook et al. 1995) to periods below the age of the trees. Thus, further progress in standardization and chronology building has been towards retaining as much low- and medium-frequency climatic information as possible while mitigating (1) the noise inherent in tree-ring series and (2) biases and trend distortion from statistical procedures. We will elaborate on some of the more recent developments that have been especially important in dendroclimatology: the regional curve standardization (RCS), signal-free standardization methods, and the combined step and trend (CST) intervention approach.

Regional Curve Standardization

Regional curve standardization (RCS) was popularized in dendroclimatology primarily by Briffa et al. (1992), and its primary goal was to recover more low-frequency variability in tree-ring chronologies for understanding changes in climate from a long-term perspective. This method aligns individual series by age and then compares each ring width with a regional curve representing an “expectation of growth” to produce indices. For more specifics on computation, please refer to Briffa and Melvin (2011). The RCS method can recover more low-frequency information than other curve-fitting methods of standardization because indices from the latter are forced to have an equal mean (1995), whereas RCS allows for varying index series means through time (Briffa et al. 1992; Briffa and Melvin 2011). There are several important limitations and potential biases to consider when using RCS to produce a site chronology: the “trend-in-signal,” the “differing-contemporaneous-growth-rate,” and the “modern-sample” bias. Briffa and Melvin (2011) describe these biases in detail. In short, the “trend-in-signal” problem occurs when climate signals nearing or extending beyond the full length of

the chronology remain in the RCS mean, thereby under or (over) estimating the final chronology at the beginning and end. This bias can be reduced, in part, by having many overlapping series. The “modern-sample” bias, which is related to the “contemporaneous-growth-rate” problem, should also be seriously considered before using RCS. This bias occurs as a result of the relationship between growth rate and tree longevity. For example, if the number of fast-growing young trees is proportionally greater than slow-growing old trees in a set of all living trees, there will be a positive trend bias in the final chronology. Despite these biases, this standardization method is very powerful for retaining low-frequency variability beyond other methods if the input tree-ring data is appropriate. The RCS performs the best when there are (1) pith-offset estimates in the case where pith dates are not achieved, (2) a sufficient number of samples (Melvin 2004), and (3) many overlapping series of subfossil wood to account for issues with the “trend-in-signal” and “modern-sample” biases.

Signal-Free Method

The signal-free (SF) method introduced by Melvin (2004) and Melvin and Briffa (2008) seeks to reduce the effect of trend distortion that has been recognized using other standardization methods (both traditional and RCS). Trend distortion occurs when variance in tree-ring measurements related to climate is removed during the process of removing age-size growth trends with data-adaptive curve fitting (Melvin 2004). This method produces a series of signal-free measurements, which are void of the common (climate) signal, and develops detrending curves based on the age-size growth-related trend of the signal-free measurements; these detrending curves are applied to the original measurements, thereby producing new indices, and the entire process is iterated as many times as needed until convergence is attained and a final chronology (with reduced trend distortion) is produced. In the effort to infer past climate while preserving low-frequency variability, recent studies have implemented and adopted the SF method (Anchukaitis et al. 2013) or even combined SF with RCS (Björklund et al. 2012). The signal-free method in conjunction with RCS might retain more low-frequency information while also helping to mitigate some of the potential biases imparted on final chronologies from RCS (Briffa and Melvin 2011).

Combined Step and Trend (CST) Intervention Approach (by Daniel Druckenbrod)

In closed-canopy forests, scientists have long observed that understory trees may experience a rapid increase in growth with removal of the canopy above them (e.g., Marshall 1927). This growth increase is typically referred to as a release from suppression (Oliver and Larson 1996) as the tree experiences greater light availability, which in turn provides greater growth. Light availability constitutes an important nonclimatic forcing of tree growth in these forests and is one example of a larger class of disturbance events (e.g., ice storms, insect defoliations, etc.) included within a common conceptual model of tree growth (Graybill 1982; Cook 1987). Identifying and removing disturbance forcings has been challenging for limiting noise in standardizing tree rings. Time series analysis (Box and Jenkins 1970) provides a statistical framework for quantifying the behavior of systems through time, particularly autocorrelated series like tree rings, and has led to advances in climate reconstruction (e.g., Cook and Kairiukstis 1990; Fritts 1976). Downing and McLaughlin (1990) demonstrated that time series analysis with intervention detection could also be applied to identify disturbance events (i.e., interventions) as step outliers in time series when examining red spruce decline; however, few studies have utilized this approach (see Druckenbrod 2005). Druckenbrod et al. (2013) introduced a new combined step and trend (CST) outlier approach that is capable of identifying disturbance events in time series and removing their impact on the subsequent growth rates of trees. After power transforming, removing the age-size growth trend,

and estimating the autoregressive order of a tree-ring time series, this method iteratively searches for outliers in the means of residuals with a running window specified by the user. Disturbance events causing growth suppressions can also be detected similar to Downing and McLaughlin (1990). While this method is new, it also shows potential for use in standardizing tree rings, possibly along with other methods such as RCS and signal-free, since it shares a common framework in time series analysis.

Pseudoproxy Experiments

Pseudoproxy experiments (e.g., Mann and Rutherford 2002) have been recently conducted by Anchukaitis et al. (2013) to evaluate the appropriateness of a set of detrending approaches to minimize the loss of low-frequency variability and trend distortion in real data when reconstructing the target climatic variable. The first step is the generation of a set of artificial pseudoproxies created by a combination of known pseudoclimate signals and growth curves with random noise. The second step is the standardization of these pseudoproxies with different methods (e.g., data-adaptive curves, RCS, or signal-free). Finally, comparisons between the known pseudoclimate and the pseudoclimate estimated with the pseudoproxies standardized in different ways can be achieved. This method allows for detecting potential artifacts directly derived from the chosen detrending method.

Tree-Ring Parameters

Stable Isotopes

The application of **stable isotopes** in tree-ring research continues to be an emerging field (Gagen et al. 2011), but one with great promise for yielding a better understanding of climatic controls and physiological processes driving growth patterns of forests. Significant relationships between well-replicated, absolute-dated tree-ring isotopic chronologies and environmental variables have been well demonstrated in paleoclimatic research (Robertson et al. 2008). Stable isotopic ratios can potentially record climatic variability at all temporal frequencies, and statistical age/geometry detrending is not required (McCarroll and Loader 2004; Gagen et al. 2007; Young et al. 2011; but see Esper et al. 2010). This is a big advantage considering the issues associated with detrending methods (as described above) for generating tree-ring chronologies based on the classical parameters (ring width and maximum latewood density). Indeed, stable isotopic signatures in tree rings can complement the traditional metrics used in dendroclimatology; they can provide a broader spatial signal, preserve low frequencies of climate variability, and reflect different climatic variables (Gagen et al. 2011) for different seasons. Stable isotopes in tree rings are strongly related to climate and atmospheric dynamics and, thus, are powerful paleoclimatic proxies that in some cases record stronger climatic signals than the classical parameter of ring width (Andreu et al. 2008; Gagen et al. 2011).

R denotes the ratio of the heavier isotope (e.g., ^{13}C) to the lighter (e.g., ^{12}C), and it is expressed in delta (δ) notation in parts per thousand (‰) with reference to a standard material of known isotopic ratio:

$$\delta_{\text{sample}} = \left[\frac{R_{\text{sample}}}{R_{\text{standard}}} - 1 \right] \times 1,000$$

The chosen standard for d_{13}C was a subfossil belemnite from the Pee Dee formation of South Carolina, which was exhausted and replaced by Vienna Pee Dee Belemnite or VPDB (Coplen 1995). The $\delta^{18}\text{O}$ signatures are in relation to the Standard Mean Ocean Water (SMOW), now replaced by Vienna-SMOW or V-SMOW, and less often, the Standard Light Antarctic Precipitation (SLAP) can

also be used (IAEA 1995). The hydrogen isotopes (the lighter ^1H , and the heavier ^2H or D, also called deuterium) are expressed as the D/H ratio (δD) and use the same reference materials as $\delta^{18}\text{O}$ ratios (IAEA 1995). Carbon and oxygen stable isotopes are the most frequently used in tree-ring research, and occasionally hydrogen. Here we primarily discuss carbon, but we direct readers to McCarroll and Loader (2004) for a more extended discussion of oxygen and hydrogen.

Stable carbon isotopes can supply distinct types of physiological information including intrinsic water-use efficiency or intercellular CO_2 concentrations to study physiological responses of trees to environmental changes (e.g., Feng 1998; Saurer et al. 2004; Waterhouse et al. 2004; Peñuelas et al. 2010; Andreu-Hayles et al. 2011). The physiological basis of $\delta^{13}\text{C}$ isotopic signatures in tree rings involves several processes and assumptions. Carbon isotope discrimination against ^{13}C (Δ) is calculated expressing the difference in isotopic composition between air ($\delta^{13}\text{C}_{\text{air}}$) and plant organic matter ($\delta^{13}\text{C}_{\text{tree}}$) in ‰ (Eq. 1). For C3 plants, the relationship between Δ and leaf gas exchange can be described by the Farquhar et al. (1982, 1989) model in Eq. (2).

$$\Delta = \frac{\delta^{13}\text{C}_{\text{air}} - \delta^{13}\text{C}_{\text{tree}}}{1 + \delta^{13}\text{C}_{\text{tree}}/1,000} \quad (1)$$

$$\Delta \approx \delta^{13}\text{C}_{\text{air}} - \delta^{13}\text{C}_{\text{tree}} = a + (b - a) \frac{c_i}{c_a} \quad (2)$$

The terms c_i and c_a are the needle intercellular spaces and ambient concentrations of CO_2 ($\mu\text{mol mol}^{-1}$), respectively. Isotopic fractionation is based on two main steps: diffusion (4.4‰) and carboxylation by the photosynthetic rubisco enzyme (~27‰; Farquhar and Richards 1984). First, air diffuses through stomata into the intercellular air spaces towards the carboxylation sites. The CO_2 with the lighter carbon isotope diffuses more easily. Thus, internal air is depleted in ^{13}C relative to ambient air. Second, CO_2 is used by the rubisco and discrimination against $^{13}\text{CO}_2$ is taking place, since biological processes tend to use ^{12}C in preference to ^{13}C .

Knowing Δ , c_i/c_a , and c_i , the intrinsic water-use efficiency (iWUE) can be estimated. Δ can be calculated using extrapolations of $\delta^{13}\text{C}_{\text{atm}}$ mainly derived from Antarctic ice-core records (Francey et al. 1999) and direct measurements, summarized by McCarroll and Loader (2004). The c_i can be determined using the data of the c_a from Robertson et al. (2001) until 1993 and from Mauna Loa from 1994 to 2007 (composite series published in McCarroll et al. (2009)). The iWUE is the ratio of the fluxes of net photosynthesis A and conductance for water vapor $g_{\text{H}_2\text{O}}$ (Ehleringer et al. 1993; Feng 1999):

$$\text{iWUE} = \frac{A}{g_{\text{H}_2\text{O}}} = (c_a - c_i) \frac{1}{1.6}$$

While some fractionation processes such as those due to CO_2 diffusion into the stomata and carboxylation (see above) are constant and consequently insensitive to climate (McCarroll and Pawellek 2001), others are determined by changes in the environment. Stable carbon isotopes ($\delta^{13}\text{C}$) in tree rings are excellent recorders of variations in climatic conditions as a result of a balance between stomatal regulation due to changes in moisture availability and photosynthetic rates and are a unique and independent resource of long-term information on the physiological status of natural forests. Stable oxygen isotopes ($\delta^{18}\text{O}$) reflect the source of precipitation and also climatic information driven by variations in the vapor pressure deficit that controls stomatal conductance. The

hydrogen isotopes δD are influenced by the same environmental factors as the $\delta^{18}O$ ratios, and so they are the result of similar fractionation process.

A downside of using the isotopes approach as compared to traditional morphological measurements is that stable isotope analyses are relatively more labor intensive to produce and more expensive, typically limiting the total number of measurements that can be reasonably performed. In recent years, however, technical improvements are beginning to successfully circumvent this limitation (e.g., Wieloch et al. 2011). There are several laboratory protocols for isotopic analysis, and here we describe some of the most commonly used methods. The isotopic composition can be measured directly from the wood, but α -cellulose is commonly extracted in order to avoid isotope variations due to other wood components (e.g., lignin or resins). This extraction uses acetic acid, sodium chlorite, and sodium hydroxide (Loader et al. 1997; Loader et al. 2003; Rinne et al. 2005) or nitric acid as described in the Brendel method (Brendel et al. 2000; Anchukaitis et al. 2008). Several methods can be applied for obtaining homogeneous cellulose in relation to its isotopic signature such as mechanical grinding of wood, cellulose freeze-milling with liquid nitrogen or an ultrasonic treatment (Laumer et al. 2009). Pooling can be done with wood from two radii per tree in order to account for isotopic variability around the circumference of a given ring (Leavitt 2010) and to ensure enough material for the analyses. Although pooling with wood from different trees is also a well-accepted method (Leavitt 1984, 2008) that saves time and resources, if applied, there is a lack of information from individual trees that precludes any chance of determining the range of uncertainty of the resulting isotopic site chronology. Finally, the cellulose samples need to be converted to sample gases to be analyzed using isotope ratio mass-spectrometers (IRMS). This gas conversion can be done off-line or online as a part of a continuous flow method that interfaces an elemental analyzer with IRMS. The implementation of online methods has greatly improved the efficiency of the entire process, substantially increasing the possible total number of measurements, a prior limitation to produce long-term records based on isotopic ratios. Stable carbon isotopes (^{13}C and ^{12}C) are measured by combusting small amount of α -cellulose placed into tin capsules to CO_2 in to the elemental analyzer (EA) coupled with an IRMS, whereas samples are placed in silver capsules for measuring stable oxygen isotopes (^{18}O and ^{16}O) using conversion via pyrolysis to CO with a high temperature conversion/elemental analyzer (TC/EA). Some recent technical improvements also can allow measuring both isotopes at the same time using pyrolysis (Knoller et al. 2005). The measurements of hydrogen isotopes (1H and $^2H/D$), both online and off-line, involve some complexities that have prevented progress in technical advancements. As a consequence, the amount of δD data available is still limited in comparison to $\delta^{13}C$ or $\delta^{18}O$ data. Detailed description of mass spectrometry methods, for each stable isotope ratio, can be found in the McCarroll and Loader review (2004).

Wood Anatomy and High-Resolution Imaging

The study of specific features within annual tree rings has also proven to be valuable for understanding and reconstructing links between tree growth and environmental conditions, particularly at intra-annual time scales. Measuring wood characteristics, like the width of the earlywood and latewood for each tree ring, as a source of specific and intra-year climatic information, has recently advanced (e.g., Meko and Baisan 2001; Griffin et al. 2011). On a finer microscopic scale, much information can be attained about past climatic and ecological conditions through careful observation of specific anatomical features within individual rings. This investigation of tree-ring anatomy can be quantified by measuring and counting structural wood components. Quantitative wood anatomy (QWA) combines traditional wood anatomy with dendrochronological techniques and provides temporal records of what often used to be only qualitative information. Many wood anatomists did not traditionally study these two disciplines in unison (Schweingruber 2007; Fonti et al. 2010), but QWA is currently

rising in importance and popularity. Recent improvements in image analysis capabilities have allowed QWA to flourish as a field of research within the past few decades (Fonti et al. 2010). Measurable parameters for conifers have included tracheid cell area and diameter, cell wall thickness, lumen diameter, and number of tracheids, which can also be measured separately for earlywood and latewood (e.g., Vysotskaya and Vaganov 1989; Fillion and Cournoyer 1995; Deslauriers and Morin 2005; Martin-Benito et al. 2013). For angiosperms, the number or density of vessels, conductive area, and vessel area, for example, can be measured (e.g., Woodcock 1989; Fonti and Garcia-Gonzalez 2004; Campelo et al. 2010). Please refer to Fonti et al. (2010) for a comprehensive listing of several wood anatomical studies, including the parameters and climatic signals identified in each study. Such features as traumatic resin ducts and frost rings can also record changes in environmental conditions and can be useful indicators of extreme events in the past (e.g., LaMarche and Hirschboeck 1984; Wimmer 2002; Bollschweiler et al. 2008). Additionally, some wood anatomical studies have identified and described anatomical features in relation to other classical dendrochronological parameters, particularly measurements of density (Yasue et al. 2000; Wang et al. 2002) due to the relation between the latter and characteristics of the cell walls. QWA can complement traditional tree-ring parameters as well as deepen and improve our understanding of linkages between tree growth and the environment over time.

Conclusions

Methods used in the field of dendrochronology have advanced significantly over the past few decades. First, standardization processes designed to obtain as much low-frequency climatic information as possible have advanced through different data treatment methods, such as the RCS and SF methods. Additionally, there are improvements on identifying and standardizing tree-ring series with disturbance signals, particularly for closed-canopy forests. Second, stable isotopes in tree rings continue to emerge as an additional parameter for understanding environmental changes in the past climatic variability, and advances in cellulose extraction and sample processing have recently made isotopic analysis more accessible. In terms of wood anatomy, improvements in image processing technology have resulted in more potential for investigating and quantifying anatomical features in tree rings. All of the aforementioned methodological advances in dendrochronology illustrate that there has recently been significant progress in the field, and it indicates that there will likely be more scientific progress in the years to come.

Radiation Dose Rate

Grzegorz Adamiec*

Institute of Physics – Centre for Science and Education, Silesian University of Technology,
GADAM Centre, Gliwice, Poland

Definition

Radiation dose rate is ionizing radiation energy absorbed per unit of time per unit of mass of the absorbing matter.

Introduction

When radiation travels through matter, it interacts with the matter. As a result of those interactions, the energy of radiation may be absorbed by the matter. Numerous physical processes are responsible for the absorption of radiation energy, depending on the type of radiation. In connection with scientific dating methods, the term dose rate is particularly relevant to trapped charge dating techniques, i.e., luminescence (OSL – optically stimulated luminescence, TL – thermoluminescence) or electron spin resonance (ESR) dating. The determination of absorbed dose and dose rate is the subject of dosimetry which plays a particular role in medicine and the nuclear industry. A comprehensive introduction to dosimetry and associated problems is given by Attix (2004).

In SI units the absorbed dose rate is expressed as 1 Gy/s, where 1 Gy (Gray) is 1 J of radiation energy absorbed by 1 kg of the absorbing matter. In older work, the CGS unit of dose rate of 1 rad/s may be encountered, which is equal to 0.01 Gy/s. The absorbed energy concerns this part of the radiation energy which is used to increase the internal energy of matter, i.e., its temperature.

Ionizing radiation can be divided into two categories:

- Directly ionizing radiation – this includes charged particles (electrons, alpha particles, protons, nuclei, muons) – which deposit energy in the matter through which it travels, through Coulomb interactions.
- Indirectly ionizing radiation – neutral particles (e.g., photons in the form of gamma radiation, neutrons) – which deposits its energy in a two-step process. In the first step, the particles lose some of their kinetic energy in collisions with secondary charged particles (electrons) present in the matter through which the radiation passes, and in the second step, these secondary charged particles lose their energy either through collisions or through radiation emission (e.g., bremsstrahlung – X-rays emitted as a result of deceleration of charged particles).

*Email: grzegorz.adamiec@polsl.pl

*Email: grzesadam@gmail.com

The average absorbed dose rate ($\dot{D}$) in a given finite volume (element) of the considered matter is defined by

$$\dot{D} = \frac{\Delta\varepsilon}{\Delta m \Delta t} \quad (1)$$

where $\Delta\varepsilon$ is the difference between radiation energy imparted to the considered volume and radiation energy leaving that volume, Δm is the mass of the considered volume, and Δt is the time over which this energy has been absorbed.

A device which allows the measurement of absorbed dose in a given volume is called a dosimeter. This includes devices for direct measurements (e.g., an ionization chamber with the necessary electronics) or materials whose properties allow storage of radiation energy (e.g., in the form of effects the radiation causes) and a later readout of the accumulated signal and post-determination of the total dose accumulated over the recording time. Examples of the latter may include small chips made of $\text{Al}_2\text{O}_3:\text{C}$ (carbon-doped aluminum oxide) used in OSL dosimetry or capsules with doped lithium fluoride (e.g., LiF:Mg) used in thermoluminescence dosimetry.

Dose Rate Determination

Direct measurements of dose rate within matter are a complex undertaking, especially if the knowledge of distribution on a small scale within the material and with temporal resolution is required (small volume or mass and very short time in Eq. (1)). This is due to the fact that radiation is absorbed differently depending on the density and the atomic number of the matter through which radiation passes and on the type of radiation and its energy. Therefore, if the dosimeter, or dose rate meter, is made of a different material than the one in which we want to determine the dose rate, a need arises to apply conversion calculations. In addition, if different types of radiation, of a range of energies, are present (a so-called mixed radiation field), it is difficult, if not impossible, to calibrate the devices in an absolute fashion to provide readings in Gy/s (or Gy in the case of accumulated dose). Therefore, the application of dosimeters always requires careful consideration in a given experimental setup.

On the other hand, in applications like trapped charge dating techniques, of interest is the average dose rate over the burial time of the dated geological sediment or ceramics rather than momentary dose rate. There exists a possibility to use Monte Carlo simulations to determine the distribution of dose within matter on the basis of simulating the physical phenomena during the passage of radiation through matter and the transport of secondary charged particles in matter (e.g., see Guérin and Mercier 2011, 2012; Nathan and Mauz 2008, example of application in Grine et al. 2007).

Example: Dose Rates Originating from Various Natural Sources

As already mentioned in the introduction, in relation to scientific dating methods, the concept of dose rate has a particular relevance to trapped charge dating techniques. In the Earth's crust, the major radioactive elements present are in the uranium and thorium decay series (natural uranium series consists of 99.29 % ^{238}U and 0.71 % ^{235}U by weight of natural uranium) and potassium (^{40}K). All these isotopes are emitters of gamma rays and beta particles while the two decay series also contain alpha particle emitters. In addition, the Earth is exposed to a constant flux of muons created in upper

layers of atmosphere by very high energy protons traveling from outside the solar system. Hence, the total dose rate experienced by objects on the Earth's surface consists of the contributions of alpha, beta, gamma, and cosmic radiations from these sources. The concentration of U, Th, and K is different at different points of the Earth's crust; hence, the natural dose rate varies from place to place.

Each of the types of radiation has specific issues when its dose rate in trapped charge dating is considered. These issues are related to their range and the way in which they interact with matter. The palaeodose, i.e., the total dose that would be determined by trapped charge dating techniques, is given by

$$P = \text{age} \times \left(kp_{\alpha}\dot{D}_{\alpha} + p_{\beta}\dot{D}_{\beta} + \dot{D}_{\gamma} + \dot{D}_c \right) \quad (2)$$

where p_{α} and p_{β} are factors (values between 0 and 1) related to the size of grains which are being dated (these factors take into account the dose rate being different at the surface of the grains and in their interiors); k is the effectiveness of α particles in inducing a luminescence (or ESR) signal and $\dot{D}_{\alpha}$, $\dot{D}_{\beta}$, and $\dot{D}_{\gamma}$ dose rates of α , β , γ radiation as calculated from the infinite matrix assumption (see next paragraph), respectively; and $\dot{D}_c$ is the cosmic radiation dose rate. The quantity in the brackets in Eq. (2) is the total so-called annual dose, i.e., dose rate expressed in Gy/a or Gy/ka (Gy per annum or kiloannum). It needs to be stressed that the actual radiation dose rate experienced by the grains does not contain the factor k .

The dose rates of alpha, beta, and gamma radiation are determined with the use of the infinite matrix assumption (see Fano 1954; Roesch and Attix 1968; Aitken 1985; and Guérin et al. 2012 for a critical review), i.e., under the assumption that radioisotopes are distributed uniformly in a homogenous matter surrounding the dated material (e.g., grains). In such a case, every portion of the matter absorbs as much radiation energy as it emits, as all the radiation energy is absorbed in the matter. Under this assumption, the specific activities (e.g., in Bq/kg, i.e., parent disintegrations per second per kilogram of matter) of uranium (natural U) and thorium (^{232}Th) chains and potassium (^{40}K) are determined in the material surrounding the dated grains using a chosen method and they are then converted into dose rates using factors derived under the infinite matrix assumption; the latest conversion factor values are given by Guérin et al. (2011, 2012).

In Eq. (2) the term $\dot{D}_c$ denotes the contribution of cosmic radiation attributed mainly to the flux of muons (Prescott and Hutton 1994). The dose rate from cosmic radiation varies with latitude, altitude, and depth below the Earth's surface. This contribution can be calculated from the geographical coordinates and depth of the dated sample. Although often this contribution is small, it is non-negligible, and in environments with low concentrations of radioisotopes considerable, and has to be taken into account.

The dose rate received by dated mineral grains (or artifacts) also depends on the amount of moisture, or, occasionally, carbonates present in the sediment. Water and carbonates attenuate the radiation field, and the more of these substances present, the more strongly attenuated the radiation. The effects of water content may be taken into account as suggested by Aitken (1985) and Guérin and Mercier (2012). The influence of carbonates is more difficult to assess as discussed by Nathan and Mauz (2008) and applied by Grine et al. (2007).

The assumptions of an infinite matrix are not precisely met in real contexts and they have to be considered in determining the annual dose. Particularly, in complex environments, these assumptions ought to be considered carefully. These problems include the presence of highly radioactive grains, different mineral layers of differing radioactivity, and difficult or impossible to determine levels of moisture present in the dated context.

Summary

The concept of dose rate is vital in trapped charge dating techniques with uncertainty or error being directly reflected in the calculated age. The determination of the radiation dose that has been acquired, e.g., by mineral grains, may be a complex task, requiring a range of assumptions to be made.

Definition

Dose rate: the amount of energy absorbed by a mineral that can be used as a natural dosimeter per unit time and mass, resulting from naturally occurring radiation both in the sample and its environment. Unit: Gy.a⁻¹ (more commonly given in Gy.ka⁻¹).

Radioactivity: Sources and Types

The focus of dose rate measurements in luminescence dating is to best quantify the amounts of naturally occurring radiation that a dated sample has been exposed to through time. It is well understood that naturally occurring radiation is generated by the decay of radioactive isotopes stored in rocks and sedimentary bodies that make up the Earth's surface. The most common source of such radioactive energy comes from potassium (K), uranium (U), and thorium (Th). ⁴⁰K is a radioisotope of potassium with a half-life of 1.25 10⁹ years; ²³²Th (half-life, 1.41 10¹⁰ years), ²³⁸U (half-life, 4.47 10⁹ years), and ²³⁵U (half-life, 7.04 10⁸ years) are the top members of distinct series of radioelements. ⁴⁰K decays in stable daughter products and is a source of both beta and gamma radioactivity. In comparison to the potassium decay, the radioactive series of thorium and uranium (²³²Th, ²³⁸U, and ²³⁵U) are more complex as they both comprise several alpha and beta emitters (see, e.g., Aitken 1985, for the decay schemes); gamma rays are also emitted in the de-excitation of nuclei, so these series contribute alpha, beta, and gamma dose rates. In an ideal case of a closed system, all radioelements in the series are at equilibrium, i.e., all the members of each chain have the same nuclear activity, defined by the concentration and half-life of the parent. As a consequence, the nuclear activity of all the decay series members from U and Th can be deduced from the concentration, or activity, of the parent. In typical sediments, beta and gamma dose rates contribute roughly two-third and one-third, respectively, of the total dose rates to sand-sized quartz grains; more detailed analysis of the repartition of dose rates can be found in Ankjærgaard and Murray (2007). In some cases (see below), alpha dose rates can also contribute a significant fraction of dose rates.

Beta and gamma radiations have low ionizing powers, i.e., the linear energy transfer is rather small compared to other radiation types such as alpha particles. As a consequence, both beta and gamma dose rates are commonly assumed to have the same efficiency in producing luminescence in a given mineral grain. For example, the amount of luminescence induced by a 1 Gy.ka⁻¹ beta dose rate from ⁴⁰K is assumed to be equivalent to the amount of luminescence induced by a 1 Gy.ka⁻¹ gamma dose rate from the ²³²Th series. Conversely, alpha particles are heavy, highly ionizing particles which saturate along their tracks the electron traps and recombination centers (the energy

*Email: gugu@dtu.dk

stores of the mineral grain) in the mineral grains at a much faster rate. As a consequence, their efficiency in producing luminescence per unit dose is much lower than that of gamma and beta radiations and has to be taken into account for accurate determination of effective alpha dose rates (see, e.g., Tribolo et al. 2001).

Another source dose rate to mineral grains is that of cosmic radiation. The contribution from cosmic radiation has been tabulated as a function of longitude, latitude, altitude (the two latter factors being the most influent), and burial depth of the dated samples, as the cosmic radiation is attenuated in the ground (Prescott and Hutton 1988). With a focus on burial depth, the contributions from cosmic radiation are classically grouped into a “soft” and a “hard” component. The “soft” component becomes totally attenuated within several tens of centimeters, whereas the “hard” component is capable of penetrating much further into the ground (several meters). Cosmic dose rates generally contribute a low percentage of the total dose rates (<10 % in most cases).

Infinite Matrix Approximation

The most important concept behind the calculation of dose rates in a sedimentary medium is that of the infinite matrix theory (Fano 1954; Roesch and Attix 1968; Aitken 1985). In a radioactive, homogeneous medium, whose dimensions are greater than the range of ionizing radiations, all the energy that is emitted per unit time and mass in the medium is also absorbed in the same medium. In other words, the infinite matrix dose rate in any volume of homogeneous sediment is equal to the rate of energy emitted per unit time and mass in that same volume. Ultimately, from the knowledge of the radioelements’ nuclear properties (nuclear activity, average energy emitted per disintegration), applying this assumption to a known measurement of the concentration of the main radioelements (K, U, and Th) within the volume of sediment allows one to convert these concentrations into infinite matrix dose rates for the homogeneous medium (Guérin et al. 2011).

Measurement

As a consequence, spectrometry techniques are the most widely used techniques to determine dose rates: different available techniques include high-resolution gamma spectrometry, neutron activation analysis (NAA), and inductively coupled plasma mass spectrometry (ICP-MS). In all methods the concentrations of K, U, and Th are determined for dry samples in the laboratory and resultantly converted in infinite matrix dose rates. Another set of techniques, called counting techniques, exploits the proportionality between disintegration count rates and dose rates: for example, beta counting techniques (Ankjærgaard and Murray 2007) and thick source alpha counting (TSAC), or threshold techniques used to derive gamma dose rates from portable field gamma spectrometers (Guérin and Mercier 2011). However, these techniques generally provide less information than spectra analysis, since the different contributions to the calculated dose rates are not individually quantified.

Sample Heterogeneity and Implications for Dose Rate Calculations

The infinite matrix theory assumes homogeneity of the sample environment from a radiation point of view. However, alpha, beta, and gamma radiations travel at different distances within a given

sample and around it, so this uniformity assumption has different meanings. Alpha particles have the ability to travel only short distances within a sample, at typically less than $\sim 20\text{ }\mu\text{m}$. In comparison, lighter beta particles travel up to 2–3 mm and gamma rays travel greater distances, up to 40–50 cm. Departure from homogeneity over these different scales has notable consequences on the accuracy of the corresponding dose rates. It is, therefore, of paramount importance to attempt to avoid the effects of sample heterogeneity in all stages of sample collection. Primarily this is achieved in the field stage by collecting samples from a sedimentary unit that is both uniform in grain size and composition within an area of roughly 1 m^3 and devoid of secondary processes such as pedogenesis, bioturbation, or carbonate replacement, which may act to change the rates of radiation transfer within a given volume of sediment.

One of the most common, and generally unavoidable, sources of dose rate heterogeneities is the presence of water. Primarily, water acts to dilute the concentrations of the radioelements in the sediment, hence requiring an adjustment of the dose rates when determined from laboratory measurements performed on dry samples (as in the case of, e.g., laboratory spectrometry techniques). In addition to this, electron stopping powers and photon interaction cross sections are higher in water than in typical soil constituents. The ratio of these physical quantities provides a correction factor to account for this effect (Zimmermann 1971). Aitken and Xie (1990) have averaged these ratios on the beta and gamma spectra in typical sediments, and more recently Nathan and Mauz (2008) have proposed new working values based on Monte Carlo simulations.

The general dosimetric concepts presented so far apply to most minerals dated by luminescence. However, constituent rock and/or mineral grains that make up a sedimentary unit have their own distinct characteristics in terms of dose rate determination. For example, flints usually have homogeneous spatial distributions of radioelements at the scale of both alpha and beta radiations (Schmidt et al. 2013) and are thus simple dosimeters from an alpha and beta dose rate calculation perspective. However, such rocks are often embedded in sediments of different characteristics, both in terms of chemical composition and radioactivity. Given the range of gamma rays (40–50 cm), gamma dose rates to rock samples thus mainly depend on the characteristics of their environment. As a consequence, direct measurements of gamma dose rates in the field (using either field gamma spectrometry techniques or artificial dosimeters) are often preferred to determine gamma dose rates to such samples; an alternative consists of determining gamma dose rates from sediment samples taken close to the rock samples.

Many mineral forms such as quartz and potassium feldspar that are commonly utilized in luminescence dating are more complicated in terms of dose rate determination. This is a result of their chemical composition and grain dimensions which ultimately break the key infinite matrix assumption of sample homogeneity. With focus on alpha and beta dose rate contributions, quartz grains contain very few radioelements (Vandenberghe et al. 2008) and thus represent cold spots in sedimentary matrices. In comparison, due to their high potassium content, feldspar grains act as radioactive sources themselves, which generate an internal dose rate that must be accounted for in final dose rate calculations. Internal dose rate to potassium feldspar grains can be calculated using their potassium content (Huntley and Baril 1997) together with dose rate conversion factors (Guérin et al. 2011). The self-dose fraction of the infinite matrix dose rate has been tabulated by Guérin et al. (2012). The small but significant contribution from ^{87}Rb can be calculated according to Readhead (2002) and Huntley and Hancock (2001). Finally, the diameter of the mineral (quartz and feldspar) grains commonly studied in luminescence (typically $\sim 100\text{--}250\text{ }\mu\text{m}$) is not negligible compared to the range of beta particles. As a consequence, the grains attenuate beta radiation from the surrounding matrix. Grain-size-dependent attenuation factors of external beta dose rates from the environment can be found in Guérin et al. (2012).

Due to the small range of alpha particles, they get strongly attenuated in sand-sized grains and their contribution is negligible $\sim 20\text{ }\mu\text{m}$ in the grains; furthermore, homogeneity of the environment of the grains is very difficult to assess at this scale. It is thus common to bypass potentially inaccurate dose rate determinations, to avoid working with alpha dose rates. For that matter, coarse grains are often treated with hexafluorosilicic acid (HF) to remove the outer rim of the grains, which has been irradiated by alpha particles, and thus eliminate the alpha dose rate contribution. For smaller grains, however, where chemical etching is not possible, a proper assessment of alpha dose rates and of alpha particle efficiency in luminescence production is crucial.

Current Investigations

The infinite matrix assumption is a very powerful tool in deriving dose rates from rocks and sedimentary units. Although fundamentally set in principle, it does allow for small departures from the concept of sample homogeneity through variations in water content and grain size. In particular, the infinite matrix assumption has been of significant use when applied to the dating of ceramics, where quartz grains are included in a uniform clay matrix at the scale of alpha and beta radiations. However, the current focus of luminescence dating has shifted to the dating of sediments where the requirements of the infinite matrix assumption are rarely met. For example, the presence of sand-sized feldspar is problematic in deriving infinite matrix dose rates, due to their non-negligible size compared to beta ranges which acts to absorb some amount of radiation and hence reduce the relative levels of radiation in other localized minerals.

Furthermore, the use of grain-size attenuation factors to calculate beta dose rates to quartz grains is based on the assumption that quartz grains represent nonradioactive inclusions in an otherwise uniform, radioactive matrix (as is the case, e.g., of sand-sized quartz grains surrounded by clay in pottery). In a sand dune, where quartz grains are the main constituent of the sediment, such a uniform matrix surrounding the grains does not exist; small grains will attenuate beta radiation less than coarse grains, but this is a relative effect, and therefore, the use of classical dose rate attenuation factors is not suited for absolute dose rate calculations (see Guérin et al. 2012).

Because of these problems related to spatial variations in dose rates, especially at the range of beta particles, some research in the field is devoted to the development of numerical and experimental methods to characterize and quantify sources of radioactivity (see, e.g., Rufer and Preusser 2009). In particular, the spatial distribution of dose rates, in relationship with the distribution of natural dosimeters (e.g., quartz grains), is a field of special interest. It is well known that some of the dispersion in single grain OSL equivalent dose distributions arises from heterogeneities of radioactivity at the scale of beta radiations: grains close to a beta source such as a potassium feldspar grain will receive a higher dose rate during burial than grains more distant from such sources. However, until now only few models have been proposed to quantify dose rate distributions at the single grain level. Mayya et al. (2006) modelled such distributions arising from the presence of potassium feldspar grains in sand made of $200\text{ }\mu\text{m}$ quartz grains; they have shown that potassium concentration in such environments is an important factor because as the potassium content is decreased, the average distance between source (potassium feldspar) and dosimeter (quartz) is increased. As a result, few grains located close to the sources will receive high dose rates, whereas most quartz grains will receive small beta dose rates, which leads to dispersion in dose rate distributions to single grains of quartz. However, more focused studies are required in order to identify the different factors driving the dispersion of dose rates. Such studies would then allow direct comparisons between equivalent dose and dose rate distributions at a single grain level and

thus allow distinguishing the different factors of dispersion in equivalent doses, for example, insufficient bleaching at the time of sediment deposition.

At a gamma dose rate scale (10 cm and more), important spatial variations may occur, for example, at the interface between sediment and bedrock or between sediment and air when samples are taken close to the surface. The presence of rocks in sediments may also influence gamma dose rate to luminescence samples. For example, it is well known that limestone is generally less radioactive than other sediment types such as clay. In complex environments where calcareous lumps are found in fine sediments richer in radioelements, Brennan et al. (1997) have thus recommended using in situ gamma dose rate measurements to obtain representative measurements.

In closure, one of the main problems in dose rate estimation lies in the evolution of this physical quantity with time: present-day dose rates may not be representative of the sample history. Water circulation, for example, can induce movement of radioelements in sediments. ^{238}U can be soluble in some environments as well as ^{226}Ra and this can cause disequilibrium in uranium series. ^{222}Rn has a short half-life (3.8 days) and is gaseous, so it can easily escape from the ground when surface is exposed to open air. High-resolution gamma spectrometry and alpha spectrometry can reveal differences in the activity of different members of the decay chain; in such cases, different scenarios for the origin of the disequilibrium can be investigated (e.g., Guibert et al. 2009) and then dose rate variations in time can be accounted for.

Synonyms

Infrared-stimulated luminescence (IRSL); Optical dating; Optically stimulated luminescence (OSL); Thermoluminescence (TL)

Definition

Luminescence dating: A family of chronologic methods typically applied to the commonly occurring minerals quartz and feldspar, which exploits a time-dependent signal that builds up in mineral grains by exposure to naturally occurring ionizing radiation (principally from uranium, thorium, and potassium). The methods assess the time elapsed since these mineral grains were last exposed to sunlight or to heating. In the case of marine and lacustrine sediments, the event being dated is the last exposure to sunlight, i.e., typically the time of deposition of the sediments.

Deep-sea, marine: Of or pertaining to the deeper parts of the sea or ocean (as opposed to shallow waters and coasts).

Lacustrine: Of or pertaining to lakes.

Introduction

Despite the fact that marine sediments were among the first sediments from which a luminescence signal was observed (Wintle and Huntley 1979), subsequently little work has been done using luminescence to date marine sediments. Similarly, surprisingly little work has been done to apply luminescence procedures to date lacustrine deposits, in spite of the rapid development, the widespread uptake, and the improved accuracy and precision of luminescence dating when applied to a wide variety of other depositional settings. The reasons behind this reluctance to use luminescence techniques to provide ages for marine and lacustrine sediments share some common links, and the challenges faced in dating these water-lain sediments are similar. It is therefore appropriate that these two depositional environments are considered together.

Historical Overview of Luminescence Dating in Deep-Sea Marine and Lacustrine Environments

Deep-Sea and Marine Sediments

The term “luminescence dating” is a broad concept which has itself developed over time, and today the term actually incorporates a family of methods which have been developed over the last

*Email: hmr@aber.ac.uk

~35–45 years for dating in different settings including sedimentary environments. These various luminescence dating methods use different signals (some of which are stimulated by heat, “thermoluminescence” (TL), and some by light, “optically stimulated luminescence” (OSL)) and different measurement protocols to determine the final numerical age estimate. A more detailed consideration of luminescence dating (see “► [Luminescence Dating](#)”) and its history (see “► [Luminescence Dating, History](#)”) are given elsewhere in this encyclopedia. However, it is interesting to note here that the potential of TL signals from quartz and feldspars to derive a numerical age for the time of deposition of marine sediments was first noted in the western literature using marine sediments. Wintle and Huntley (1979) observed an increasing TL signal with increasing depth for a core from the Crozet Plateau in the Antarctic Ocean and recognized that this TL signal was coming from inorganic sediment. Furthermore, they noted that exposure to sunlight could act as a mechanism for resetting the TL signal prior to deposition of the sediments. Comparing the TL ages generated against independent age control, Wintle and Huntley (1979) concluded that the findings were “sufficiently encouraging to suggest that the method is basically sound.” Following this pioneering work, TL was then rapidly applied to terrestrial sediments, particularly loess (see entry for “► [Luminescence Dating, Loess](#)” in this encyclopedia), but it was to be more than 20 years until further work was done in deep-sea or marine settings using luminescence signals of any kind.

In the intervening 20 years, luminescence dating underwent a series of radical transformations (see “► [Luminescence Dating, History](#)”), the most critical being the development of optical stimulation to yield a signal appropriate for dating sediments, and the development of sensitivity-corrected methods for measuring the luminescence signal from single aliquots (e.g., the single-aliquot regenerative dose (SAR) measurement protocol of Murray and Wintle (2000), which has subsequently been adapted and developed for various luminescence signals and materials). Following the introduction of the SAR protocol for quartz, and comparison of the ages generated against independent age control (e.g., Murray and Olley 2002; Rittenour 2008), confidence grew in the OSL signal from quartz for dating and in the ability to look at complex equivalent dose (D_e) distributions; attention could now be turned to more challenging environments, including the marine realm.

Stokes et al. (2003) were the first to apply a SAR OSL measurement protocol to quartz prepared from deep-sea marine sediments, studying cores taken from the Western Arabian Sea. The fine-grained quartz ages generated were in agreement with independent age control provided by radiocarbon, tephrostratigraphy, and paleoecological data (Stokes et al. 2003). The fine-grained (4–11 μm diameter) quartz was believed to be eolian (i.e., wind-blown) in origin, and as such is likely to be well bleached prior to deposition. Using fine grains for OSL dating precludes the possibility of investigating the degree of bleaching because of the large number ($>10^5$) of grains on each aliquot. In spite of this, it is interesting to note that Stokes et al. (2003) still observed $>4\%$ of aliquots with D_e values >3 standard deviations from the mean estimate, and they used this rather crude approach to screen and remove outlying D_e data; today a more sophisticated statistical approach would be taken (e.g., the Minimum Age Model, Galbraith et al. 1999; see “► [Luminescence Dating, Single Grain Dose Distribution](#)”). Such an approach was taken by Olley et al. (2004) who examined the degree of bleaching of sediments from the eastern Indian Ocean using single grains of fine-sand-sized (60–70 μm) quartz. In spite of being eolian in origin and having relatively long transport distances (and it would be thought, ample opportunity for bleaching), some samples were incompletely bleached on deposition. However, following appropriate statistical treatment, the single-grain quartz OSL ages generated were in agreement with independent age control provided by radiocarbon, between ~1,500 and 50,000 years ago (Olley et al. 2004). If problems of incomplete bleaching prior to deposition are found to be an issue in these nonpolar marine settings where eolian transport can dominate, it should perhaps come as little surprise that problems of incomplete

bleaching and age overestimation have also been reported in polar marine settings (e.g., Jakobsson et al. 2003; Berger 2006), where daylight can be restricted and where transport pathways are more complex and can occur in association with ice and turbid water. Nevertheless, some of these OSL ages have been found to be in agreement with the expected ages (e.g., Jakobsson et al. 2003). However, it was not possible to develop criteria based on luminescence evidence alone by which accurate and inaccurate luminescence ages could be distinguished.

More recently, quartz grains of fine-silt (4–11 μm), coarse-silt (~ 38 –63 μm), and fine-sand (63–90 or 90–125 μm) size have been analyzed in nonpolar deep-sea marine settings, and these yield SAR OSL ages which are typically in agreement with independent age control or expected ages, e.g., the Sea of Okhotsk (Sugisaki et al. 2010a, b) and the south Bohai Sea, China (Yi et al. 2012a, b). A notable exception is the work undertaken in the south Bohai Sea where radiocarbon ages of 38–44 cal kyr BP have been used to assign a particular sedimentary unit to Marine Oxygen Isotope Stage (MIS)-3 (Liu et al. 2009), while OSL ages suggest that the unit actually relates to MIS-5 (Yi et al. 2012b) and hence imply that the radiocarbon ages may be at the limit of the method and thus unreliable. This example highlights the potential value of luminescence dating in any depositional setting where it can be used to extend the numerical chronology for a sedimentary sequence beyond the upper (and indeed lower) limit of radiocarbon dating. Where agreement can be established between luminescence ages and any other independent chronology in a time span clearly appropriate for both methods (e.g., in Holocene sediments from the south Bohai Sea; Yi et al. 2012b), then there is additional confidence that as one chronometer approaches its limit, then the second chronometer can be used to extend the chronology.

In carbonate-restricted zones such as high-accumulation-rate deposits where there is a lack of biogenic material, and in deep areas of the oceans below the carbonate compensation depth (CCD), there is even greater incentive to use luminescence techniques to generate a numerical chronology. Given the relatively limited number of luminescence dating studies conducted thus far in marine settings, further studies are probably required in order to build up confidence in the ability of luminescence dating to generate accurate ages in settings where no independent chronology exists. However, the initial studies that have been conducted are extremely promising.

Lacustrine Sediments

Lakes preserve some of the best terrestrial records of climate and environmental change on Earth, containing numerous proxy records which can be seen to vary over time. Surprisingly little work has been done to apply luminescence techniques to date lacustrine sediments. Instead, such sediments have hitherto primarily been dated using radiocarbon techniques, and extrapolation is frequently used to infer the age of sediments beyond ~ 40 –50,000 years ago (e.g., Burnett et al. 2011). However, given the potentially long time period over which lake sediments can accumulate, and the comparatively short time range over which radiocarbon can be applied, there is tremendous scope for the use of luminescence techniques for dating lacustrine deposits.

The reluctance to apply luminescence techniques to date lacustrine sediments is probably linked primarily to concerns over the degree of bleaching of the sediments prior to deposition. For this reason, where luminescence techniques have been used to date lacustrine sediments, it is primarily lake shoreline deposits (rather than lake floor sediments) that have been dated thus far (e.g., Burrough et al. 2009). These concerns over incomplete bleaching of the luminescence signals prior to deposition were particularly pertinent in the early days of luminescence dating when TL signals were used, because the TL signal is known to bleach much more slowly in nature than the OSL signal. Additionally, bleaching in the water column adds an extra layer of complication due to the turbidity of the water and the attenuation of the spectrum with increasing depth through the water

column. Lake morphology (i.e., shape) is therefore likely to be an important factor in determining the success of a lacustrine luminescence study; for example, an early study by Berger et al. (1987) demonstrated that large lakes with broad, low-gradient lake floors were likely to be most appropriate. In spite of these concerns over bleaching prior to deposition, particularly using TL signals, the successful application of luminescence dating of lacustrine sediments is demonstrated by Berger and Anderson (1994) for Squirrel Lake, Alaska, where TL and radiocarbon ages were found to be in agreement for the upper 3 m of sediment, which was within the range of radiocarbon dating; beyond this, a further 11 m of sediment was dated using TL with the maximum age being 125 ± 31 ka (Berger and Anderson 1994). The IRSL signal from feldspars bleaches more rapidly than the TL signal, and for this reason, Berger and Doran (2001) favored the IRSL signal for dating lacustrine sediments from Lake Hoare, Antarctica, which gave IRSL ages that were younger than TL ages for corresponding samples. Even though these IRSL ages were younger than the TL ages generated, there is still some question as to whether the IRSL signal was completely bleached prior to deposition because examination of a modern analogue sample (which should give an age which is essentially zero years) returned an age of ~600 years. The OSL signal from quartz bleaches even more rapidly than that of feldspar and also offers the advantage that it does not suffer from anomalous fading (which can cause age underestimation in feldspars), and hence today since the advent of SAR methods (Murray and Wintle 2000), quartz would probably be the mineral of choice for dating lake sediments. An example of the successful use of quartz OSL dating to determine the ages of lacustrine sediments is provided by Long et al. (2011) for Qingtu Lake, in northern China, where good agreement was obtained between OSL ages from coarse-silt-sized quartz and radiocarbon ages derived from shell fragments and organic-rich bulk sediments.

Although the quartz OSL signal bleaches most rapidly of all the commonly used signals from the family of luminescence dating techniques, this fast component OSL signal is also the fastest to saturate in nature, i.e., it has the youngest upper limit for dating (~150 Gy (Chapot et al. 2012), which is likely to correspond to a maximum age for lacustrine sediments of ~130 ka). For example, Lowick et al. (2010) and Lowick and Preusser (2011) generate fine-grained quartz OSL ages that are in agreement with independent biochronologic evidence to ~140 Gy (which in this study corresponds to an age of only ~70 ka), but beyond this the OSL ages are increasingly underestimated. For this reason, Zander and Hilgers (2013) explored the use of various different luminescence signals to date their Middle- to Upper-Pleistocene sediments (~145–760 ka) from Lake El'gygytgyn, Russia. In this study, the quartz OSL signals were saturated and hence gave ages which significantly underestimated the expected age based on magnetostratigraphy, and the IRSL signals measured at 50 °C from polymineral fine grains also gave rise to age underestimations throughout the study for similar reasons. The thermally transferred OSL ("TT-OSL") quartz ages were also unsatisfactory as they were found to be of variable reliability. However, ages generated using a post-IR IRSL₂₉₀ measurement protocol (Thiel et al. 2011) which minimizes anomalous fading were in agreement with the expected ages back to ~465 ka and potentially even to ~760 ka (Zander and Hilgers 2013).

Practical Considerations, Concerns, and Benefits of Using Luminescence Techniques to Date Deep-Sea Marine and Lacustrine Sediments

Several practical considerations and concerns have contributed to the slow uptake of luminescence techniques for dating deep-sea marine and lacustrine sediments. However, there are several key benefits offered by luminescence dating which it can be argued now outweigh these concerns.

Practicalities

Deep-sea marine and lake floor sediments are typically obtained as cores, often requiring deep drilling to obtain them. This logistically complex and hence also relatively expensive method of retrieval leads to further complications. Being taken in cores, the material is often relatively limited in terms of the sample size available. The wide variety of proxies available from lake cores also means that the precious core material is required for numerous different analyses, which again restricts the amount of core material available for any one technique. In many studies, cores are often split and logged and exposed to daylight prior to sampling for luminescence dating. While light-exposed cores can still be successfully sampled for luminescence dating (by removing the outer, light-exposed portions of the core which can be used for dose-rate determination), it should be noted that X-ray scanning prior to sampling for luminescence can add a radiation dose to sample material, potentially leading to erroneous age determinations (Davids et al. [2010](#)).

Concerns

One of the principal concerns regarding the use of luminescence dating in deep-sea marine and lacustrine sediments is the accurate assessment of the water content over the post-depositional history of the sediments; this is important because water attenuates the radiation dose reaching the sediment grains and hence influences the age determination. Uncertainty in the water content is typically the largest single source of uncertainty in luminescence ages generated for deep-sea marine and lake floor sediments. The water content of such water-lain sediments can be extremely variable through the sedimentary sequence and also changes over time, with the lowermost sediments becoming increasingly compacted as new sediments accumulate above, causing dewatering and hence a reduction in water content over time. Compaction of the sediments can also occur on retrieval of sedimentary cores, and care must therefore be taken to assess the degree of compaction during the drilling process to facilitate the reconstruction of water content after sampling. It is also important to consider the changing depth of water (and sediment) above the chosen sample location within the sedimentary profile because it will influence the cosmic dose rate (and the dose rate from adjacent sediments) reaching the sample over time.

Another key concern is the degree of bleaching of any preexisting luminescence signal prior to deposition in deep-sea marine and lacustrine settings; investigating this is particularly difficult in these settings due to the typically fine-grained nature of the sediments precluding the determination of D_e values for individual grains which would otherwise be used to assess the degree of bleaching. An alternative approach is to compare the D_e values obtained using different luminescence signals from the same sample and exploit the different bleaching rates of the luminescence signals as a means of identifying incompletely bleached sedimentary units. For example, Buylaert et al. ([2013](#)) proposed using the ratio of IR_{50} and $pIRIR_{290}$ D_e values throughout a lacustrine sediment profile at Laguna Potrok Aike, Argentina, to screen out incompletely bleached samples; the ages which passed this screening criterion (29 ages out of 47 analyzed) are chronostratigraphically consistent and show good agreement with independent age control.

A further concern is the geochemistry of deep-sea marine and lacustrine settings, which can complicate the assessment of the dose rate. In such cases, the assumptions typically made regarding the presence of secular equilibrium in the uranium- and thorium-decay series chains and thus a constant dose rate (Gy/ka) over time would not hold true, and hence a more detailed assessment of the dose rate over time would need to be conducted to account for the unsupported and supported radionuclides (e.g., Stokes et al. [2003](#)).

Benefits

Given the concerns outlined above, and the relatively small number of luminescence studies in deep-sea marine and lacustrine settings thus far, it would seem prudent for new studies to have some form of independent age control for verification of the luminescence ages generated. However, this will not be possible in all cases, and indeed the lack of age control in these settings is a key motivation for applying luminescence dating here. Where other chronologic evidence does exist, it can sometimes be complicated by problems within that technique itself (e.g., radiocarbon reservoir effects). Notwithstanding these issues, luminescence dating of deep-sea marine and lacustrine sediments is becoming an increasingly attractive prospect, particularly given advances in equipment and methodology since the year 2000, and also in the accuracy and precision of the ages generated. Luminescence dating offers a number of internal quality control checks that can be performed to offer assurance of the suitability of the signals used for dating (e.g., Roberts 2008), and unlike some other methods, it is not beset by issues of calibration. Luminescence dating is also an attractive method because the two minerals principally used for dating (quartz and feldspar) are very common, so it is rarely problematic to find sufficient material for dating. Furthermore, luminescence dating provides a numerical chronology and hence allows the assessment of accumulation rates through long sedimentary sequences without the need for extrapolation and the inherent assumption of a constant accumulation rates over time periods typically from the present day to 10^5 years.

Summary and Conclusions

Relatively few studies of deep-sea marine or lacustrine sediments have taken place using luminescence dating. The most successful approach demonstrated thus far is the use of quartz OSL signals for dating, measured use of a single-aliquot sensitivity-corrected method such as SAR, although newly developed post-IR IRSL methods developed to minimize anomalous fading in feldspars also show great promise. The luminescence ages generated tend to be in good agreement with the independent age control. Given the difficulties of dating marine and lacustrine sediments using many other methods (e.g., “► [Sediments, Marine \(Palaeomagnetism\)](#),” “► [Lacustrine Environments \(\$^{14}\text{C}\$ \)](#),” “► [\$^{210}\text{Pb}\$ Dating](#),” “► [\$^{226}\text{Ra}\$ Dating, Sediment](#),” “► [Carbonates, Lacustrine, \(U-Series\)](#),” “► [Carbonates, Marine Carbonates, \(U-Series\)](#),” “► [Sedimentation Rate, Marine \(U-Series\)](#)”), and the particular problems that can be associated with the use of radiocarbon in some settings (► [\$^{14}\text{C}\$ Dating](#)), luminescence dating could potentially make an important contribution to the study of deep-sea marine and lacustrine sediments in the future.

ESR dating of sediment; ESR dating of sedimentary quartz

Introduction

As quartz is the most common mineral forming the rocks of the earth surface, its dating is of potential value. Electron spin resonance (ESR) dating of sedimentary quartz has many applications in geology and archaeology. The first studies on ESR dating of sedimentary quartz were done by McMorris in the early 1970s and then by Yokoyama et al. (1985) and Tanaka et al. (1985) and summarized by and Ikeya (1993). During the past two decades, our knowledge about the ESR dating of sedimentary quartz has improved, and this method can now be routinely used for dating alluvial sedimentary quartz deposits.

Paramagnetic Centers Used for Dating of Quartz

The silicon atom, Si, is inside four oxygen atoms forming a tetrahedral SiO_4 . In case of silica, or quartz (SiO_2), each oxygen atom is bonded with two Si atoms to form a three-dimensional network in a crystalline form. Impurity-associated defects gives ESR signals associated with impurities such as substitutional tetravalent ions (Ge^{4+} and Ti^{4+}) and trivalent ion (Al^{3+}) as well as interstitial monovalent cations, M^+ (H^+ , U^+ , and Na^+) (see Fig. 1; Weil 1984; Ikeya 1993). These paramagnetic centers, radiosensitive and with a high thermal stability, can be used as dosimeters, though the use of the Ge^{4+} center remains unclear (see below).

Formation of Al Paramagnetic Centers

In the SiO_2 lattice, trivalent aluminum ion Al^{3+} is easily substituted at a Si^{4+} site. The principle of ionic charge neutrality in an ionic crystal requires a charge-compensating monovalent cation interstitial. In this case, a monovalent cation M^+ such as Li^+ , Na^+ , and H^+ at the interstitial site is associated with Al^{3+} as a charge compensator and gives rise to a $[\text{AlO}_4/\text{M}^+]^\circ$ center. When the charge-compensated $[\text{AlO}_4/\text{M}^+]$ traps a hole created by ionizing radiation at room temperature on one of the two long-bonded oxygen neighbors, the cation M^+ diffuses away leading to $[\text{AlO}_4/\text{h}]^\circ$, where h is a hole trapped in a nonbonding 2p-orbital of oxygen located adjacent to the substitutional aluminum (O'Brien 1955; Hitt and Martin 1983 in Ikeya 1993).

Fig. 1 Impurity-associated defects present in the SiO_2 lattice

Formation of Ti and Ge Paramagnetic Centers

Ge^{4+} or Ti^{4+} substitutes for a Si^{4+} site in the SiO_2 lattice, but its electron affinity (ionization potential) is considerably larger, resulting in trapping of an electron created by ionizing irradiation to form $[\text{GeO}_4/\text{TiO}_4\text{-e}^-]^-$ in the SiO_2 lattice. The total charge of the center is -1 , and thus Ge^{3+} or Ti^{3+} at a Si^{4+} site in an SiO_2 structure has a negative effective charge, attracting an interstitial monovalent cation M^+ such as H^+ , Li^+ , or Na^+ , to form stable $[\text{GeO}_4/\text{M}^+]^\circ$ or $[\text{TiO}_4/\text{M}^+]^\circ$ at room temperature (Andersen et al. 1974 in Ikeya 1993).

Paramagnetic Center Features

Al center is commonly employed for dating as it is a radiosensitive center with a high saturation dose and it is one of the most thermally stable radiation-induced centers in SiO_2 . The ESR signal related to the aluminum can be detected in all natural quartz and used for dating sedimentary of quartz grains deposited during all the Plio-Pleistocene period (McMorris 1971; Yokoyama et al. 1985; Toyoda and Ikeya 1991; Falguères et al. 1991; Laurent et al. 1998; Toyoda and Falguères 2003; Lin et al. 2006).

Ti–Li and Ti–H center can be detected in almost all sedimentary quartz. The saturation of the Ti–H center is rapidly reached (Beerten et al. 2006; Tissoux et al. 2007, 2008). This implies that Ti–H center can be used only for the dating of samples with low palaeodoses (Upper Pleistocene deposits, or older in case of very low annual dose). Ti–Li center could be used for dating sediments of Lower Pleistocene age (Rink et al. 2007; Liu et al. 2010).

It is possible that the Ge center could be employed over the same range of ages as the OSL dating method. However, the ESR Ge signal is rarely observed in the natural samples, although growing with small artificial irradiation doses, suggesting that it is not stable over geological time scales (Rink 1997).

Ge center can be detected by ESR at room temperature, whereas Al and Ti center signals are observed at low temperature (Fig. 2).

Fig. 2 *Al* and *Ti* center measured samples measured with a JEOL PX-2300 ESR spectrometer. Temperature 80 K; microwave power 5 mW; width of the magnetic field 10 mT; modulation amplitude 0.1 mT; time constant 0.03 s.; frequency 100 kHz (After Tissoux et al. 2008, modified)

Bleaching

When dating sedimentary quartz, the geological or archaeological events have to be dated, not the quartz growth. Thus, a zeroing of the quartz geochronometer is necessary before the time of deposition of the sedimentary sequence. This zeroing is also named “bleaching.” The bleaching occurs when the energy brought to the quartz grain is sufficient to release the electron trapped in the defects (activation energy). This energy can be brought by pressure, light exposure, or heat, and the exposure has to be long enough for a maximal release of the trapped electron. Otherwise, a residual dose is inherited from the primary history of the quartz, leading to an overestimation of the dose acquired during the depositional history of the quartz grain.

Regarding marine, alluvial, or aeolian sediments, an optical bleaching by sunlight of the light-sensitive paramagnetic centers of quartz occurs during the transportation of the quartz grain by water or by wind, before deposition in the sedimentary sequence (Fig. 3).

Many authors investigated the behavior of some paramagnetic centers of quartz when they are exposed to natural or artificial light (Brumby and Yoshida 1994; Walther and Zilles 1994; Yoshida 1996; Tanaka et al. 1997; Toyoda et al. 2000; Voinchet et al. 2003; Tissoux et al. 2007, 2012).

They observed that Al centers of quartz cannot be totally bleached by exposure to the sunlight. An ESR residual dose, related to Al centers, is observed in quartz after a maximal optical bleaching and is generated by the presence of deep aluminum traps in the crystal, which cannot be reset by solar light. This residual dose must be determined for all the sedimentary quartz when ESR geochronology studies are performed. Bleaching experiments indicated that several weeks of exposure were necessary to obtain a maximal bleaching of the Al center (plateau value); the Ge center can be totally bleached in 3 h of exposure by simulated solar light; the Ti–Li center can be

Fig. 3 Optical bleaching history of *Ti* and *Al* centers in sedimentary quartz

totally bleached after a time of exposure similar to the one of Al center, whereas Ti–H center needs less than half the time to be totally bleached.

ESR Dating of Optically Bleached Fluvial Quartz Deposits

The ESR dating of alluvial quartz is based on the hypothesis of ESR trap resetting by sunlight during the transport phase in the river prior to the sediment burial. The calculated age does not correspond to the quartz crystallization but to the time elapsed since the quartz deposition in the alluvial formation.

The exposure time necessary for a maximal bleaching during transport by the river seems to be a very long exposure in natural conditions. However, studies of modern sediments deposited in sandy bars show that the maximum bleaching is effectively reached for Al center at few kilometers from the river’s spring (Voinchet et al. 2007). Liu and Grün (2011) conclude that tumbling due to fluvial transport may take a part in the resetting of the ESR centers. ESR dating of fluvial deposits has been then successfully applied using Al center of quartz (Yokoyama et al. 1985; Laurent et al. 1994; Voinchet et al. 2003, 2004). “Absolute” chronologies of alluvial systems could then be established with strong implications in archaeology (Bahain et al. 2007; Voinchet et al. 2010; Despriée et al. 2011).

ESR Dating of Optically Bleached Aeolian Quartz Deposits

Signal resetting by sunlight prior to burial is a crucial assumption in electron spin resonance (ESR) dating of sediments. This resetting process was successfully tested for Ti–Li and Ti–H signals of quartz from a contemporary desert surface deposit, demonstrating the potential of using the Ti–Li and the Ti–H centers in quartz for dating fossil sediments from similar environments (Beerten and

Stesmans 2005). On the contrary, optical bleaching experiments showed that sunlight does not completely bleach the ESR Al signal of quartz grains in aeolian sand from Australia (Tanaka et al. 1995) and in loess of northern Europe (Tissoux et al. 2010).

ESR Dating of Optically Bleached Marine Quartz Deposits

Tanaka et al. (1997) and Tissoux et al. (2008) applied ESR dating on known-age marine terrace sediments collected in Japan using Ti signal and Ti and Al signals, respectively. In both cases, it was apparent that the signal in the samples studied here had not received complete pre-burial bleaching. On the contrary, ESR dating of quartz from fossil beach in Nice, France (Falguères et al. 1988), and from fossil estuarine in the Somme Valley, France (Laurent et al. 1998), provided data in agreement with the expected ages. Burdette et al. (2013) showed that using the Ti–Li signal from sands from stranded ancient coastal deposits in Florida were in concordance with increasing geomorphic age and had ages older than OSL saturation indicated. Moreover, biostratigraphic age constraints in one sample were consistent with the ESR optical ages.

ESR Dating of Glacial Deposits

Together with sunlight bleaching, such grinding mechanisms could be an effective zeroing mechanism in ESR dating of glacially derived sediments. As such, the Ge-related impurity center in quartz was applied for the dating of Pleistocene glaciations in Central Asia (Zhou et al. 2002; Yi et al. 2002; Zhao et al. 2006, 2010). However, some fundamental points remain unclear as mentioned here above.

Summary or Conclusion

ESR applied on sedimentary quartz is a powerful dating method when applied on quartz extracted from fluvial, coastal, or desert or sediments deposited during the Plio-Pleistocene period.

Rhenium–Osmium Geochronology: Sulfides, Shales, Oils, and Mantle

Holly Stein^{a,b*} and Judith Hannah^{a,b}

^aAIRIE Program, Colorado State University, Fort Collins, CO, USA

^bCEED, University of Oslo, Oslo, Norway

Synonyms

Re–Os geochronology; ^{187}Re – ^{187}Os geochronology

Definition

Rhenium–osmium geochronology is based on radioactive decay of ^{187}Re to ^{187}Os with a half-life of 41.6 b.y. – about 10 times the age of the earth. Both Re and Os are siderophile-chalcophile elements, that is, they are both strongly partitioned into metals or sulfides rather than silicates. This distinguishes them from other widely used geochronometers whose parent-daughter elements reside in silicates. Re–Os geochronology underpins dating of materials from meteorites, the mantle, and metallic ore deposits. Furthermore, both Re and Os are redox-sensitive metals, soluble when oxidized, and fixed by reduction. Thus, both are mobile in Earth's presently oxidized surface environments but are concentrated in sulfides and organic matter in anoxic-euxinic sediments. This is the basis for Re–Os dating of the depositional age of organic-rich sedimentary rocks and provides a temporally constrained record of changing redox conditions through earth history.

Fundamentals of Re–Os Geochemistry

There are two naturally occurring isotopes of Re: stable ^{185}Re and radioactive ^{187}Re . Mass fractionation of the two Re isotopes is readily observed during the extreme conditions imposed by mass spectrometry (e.g., Suzuki et al. 2004; Zimmerman et al. 2007). The few reported natural variations, however, are less than 0.3 ‰ (Miller et al. 2009) and thus introduce errors less than other sources of uncertainty for Re–Os geochronology. As with other high-mass elements used in geochronology, we therefore assume uniform present-day abundances of ^{185}Re (37.398 %) and ^{187}Re (62.602 %; Gramlich et al. 1973) as an underpinning assumption for radiometric dating.

There are seven naturally occurring isotopes of Os: ^{184}Os , ^{186}Os , ^{187}Os , ^{188}Os , ^{189}Os , ^{190}Os , and ^{192}Os . Isotope ^{187}Os is the product of beta decay of ^{187}Re , with a decay constant of $1.666 \times 10^{-11} \text{ year}^{-1}$ (Smoliar et al. 1996). Isotope ^{186}Os is the product of alpha decay of ^{190}Pt with a decay constant of $1.542 \times 10^{-12} \text{ years}^{-1}$ (Walker et al. 1997). The abundances of the remaining isotopes may be considered constant for present-day Re–Os isotope geochemistry and geochronology. Prior to recognition of small, but measurable contributions of radiogenic ^{186}Os , Os isotopic compositions were reported as $^{187}\text{Os}/^{186}\text{Os}$. Current convention is to normalize abundances of ^{187}Os to ^{188}Os , reporting isotopic variations in terms of the ratio $^{187}\text{Os}/^{188}\text{Os}$.

Fig. 1 Reservoirs important to the terrestrial Re–Os budget

Os is highly compatible in mantle sulfides and metal alloys and is thus strongly sequestered in the earth’s mantle relative to the crust. Re, in contrast, is only mildly compatible and is therefore transferred to the crust by partial melts far more efficiently than Os (e.g., Reisberg and Lorand 1995). Thus, $^{187}\text{Re}/^{188}\text{Os}$ ratios in fertile (undepleted) mantle are low (about 0.4), whereas $^{187}\text{Re}/^{188}\text{Os}$ ratios in the crust are much higher and extremely variable; crustal $^{187}\text{Re}/^{188}\text{Os}$ averages about 50 and ranges from one to three orders of magnitude (or more) higher than the mantle (Shirey and Walker 1998). The extreme variability in $^{187}\text{Re}/^{188}\text{Os}$ ratios offers two key opportunities. First, because $^{187}\text{Re}/^{188}\text{Os}$ ratios are markedly higher in the crust than in the mantle, decay of ^{187}Re over time produces an enormous range of $^{187}\text{Os}/^{188}\text{Os}$ ratios in crustal materials. This provides a sensitive tracer of crustal input to mantle or crustal contamination in mantle-derived materials. Second, extremely high $^{187}\text{Re}/^{188}\text{Os}$ ratios in some materials make them suitable for dating very young samples, despite the long half-life of ^{187}Re .

Figure 1 illustrates earth’s Re and Os reservoirs and Fig. 2 details the Re–Os budgets in various reservoirs, along with the potential for cycling among those reservoirs. Whereas subduction cycles crustal Re and Os into the mantle, partial melting and slab dehydration introduce the elements into the crust. The oceans receive Re and Os from seafloor hydrothermal processes, seafloor weathering, riverine inputs from continental weathering, rain of cosmic dust, and the occasional meteorite. Present-day input from continental weathering constitutes about 80 % of the Os budget of seawater (Sharma et al. 1997).

Fundamentals of Re–Os Dating: From Sample to Age

Analyses for high-precision Re–Os ages are acquired using the isotope dilution method, in which a known amount of one isotope of each element is added to the sample prior to analysis. Given the amount and composition of the isotopic “spike” added and the measurement of isotopic ratios in the mixture, it is straightforward to calculate the ratios in the sample. For example, the weight in μg of Re in a sample can be calculated as follows:

$$\text{Re}_w = \text{Spk}_w \frac{AW_{\text{sam}}}{AW_{\text{spk}}} \left[\frac{^{185}\text{Re}_{\text{spk}} - R_M^{187}\text{Re}_{\text{spk}}}{R_M^{187}\text{Re}_{\text{sam}} - ^{185}\text{Re}_{\text{sam}}} \right] \quad (1)$$

Fig. 2 Re and Os reservoirs with sources and sinks for seawater (From Hannah and Stein 2012). Riverine concentrations of Re and Os depend strongly on the composition of bedrock in the drainage area; flux to the oceans is a mixture of dissolved and suspended load. Therefore, global averages are not available. Data are summarized from a variety of sources, all cited in the main text

where Re_w = weight of Re in the sample, Spk_w = weight of Re in the spike (same units as sample), AW_{sam} = atomic weight of Re in the sample, AW_{spk} = atomic weight of Re in the spike, $^{187}Re_{spk}$ and $^{185}Re_{spk}$ = fraction of each isotope in the spike, $^{187}Re_{sam}$ and $^{185}Re_{sam}$ = fraction of each isotope in the sample, and R_M = measured $^{185}Re/^{187}Re$ ratio. Dividing Re_w by the weight of the sample in grams yields the concentration of Re in μg per gram, or ppm. Derivations, explanations, and examples of applications for this and many other calculations based on isotopic data are given in Faure and Mensing (2005).

Today, isotopic analyses of Re and Os are most commonly acquired in three steps: (1) dissolution of the sample and equilibration with isotopic spikes in a closed vessel; (2) chemical purification of Re and Os, separating each from the matrix and from each other; and (3) isotopic analysis of each element by negative thermal ionization mass spectrometry (NTIMS). For Step 1, the sample and spikes are loaded into thick-walled Pyrex tubes (Carius tube) with inverse aqua regia, sealed, and equilibrated for at least 24 h at 240 °C (Shirey and Walker 1995). To isolate organic matter or sulfides in shale samples without dissolving or significantly leaching detrital minerals, a solution of $CrO_3-H_2SO_4$ is used in place of inverse aqua regia (Selby and Creaser 2003; Kendall et al. 2004).

For Step 2, Os is separated from the solution in the Carius tube either by distillation (Morgan and Walker 1989) or dissolution in an organic phase (CCl_4 or $CHCl_3$) and back extraction into HBr (Shen et al. 1996; Cohen and Waters 1996; Brauns 2001), followed by microdistillation (Roy-Barman and Allègre 1995; Birck et al. 1997); both utilize the volatility of Os under oxidizing conditions and its quantitative drawdown into HBr. Re is subsequently purified on ion exchange columns (Morgan and Walker 1989).

For Step 3, although NTIMS is almost universally used for high-precision measurement of Os isotopes, some labs use solution multi-collector inductively coupled plasma mass spectrometry (MC-ICP-MS) to determine the Re isotopic ratio. Spot analyses, such as laser ablation MC-ICP-MS for Re–Os isotopic analyses, are not feasible in most cases for one or both of two reasons. First, most Os concentrations and some Re concentrations are too low, below detection limits for LA-MC-ICP-MS. Second, in some materials – notably in molybdenite – the radiogenic daughter isotope ^{187}Os may diffuse and collect in crystal defects, so that it is spatially decoupled from its parent ^{187}Re (Stein

et al. 2001, 2003; Košler et al. 2003; Selby and Creaser 2004). The resulting ages may be highly erroneous, either too old or too young (see discussion in later section).

Prior to interpretation of the isotopic data, raw measurements of isotopic ratios from mass spectrometry are corrected for instrumental mass fractionation, and all analytical uncertainties must be identified and appropriately calculated. Mass fractionation of Os isotopes is readily corrected for each measurement by using $^{190}\text{Os}/^{188}\text{Os} = 3.08271$ (Platzner 1999). Because Re has only two isotopes, however, and ^{185}Re is introduced as an isotopic spike, there is no stable, unchanging isotopic ratio in the sample to measure. If MC-ICP-MS is used, however, the sample can be doped with an element of similar atomic weight that has at least two stable isotopes, typically Ir or W, and the mass fractionation of those isotopes used to correct for that of ^{185}Re and ^{187}Re (e.g., Schoenberg et al. 2000; Li et al. 2010). For NTIMS, Re isotope fractionation is determined from repeated measurements of a standard and assumed to be the same for sample analyses. Measured ratios are corrected for mass fractionation and isobaric interferences. Other sources of uncertainty in Re–Os analyses arise from weighing, standard and spike calibrations, and blanks. The 2σ uncertainties for Re and Os abundances and the isotopic ratios are calculated by numerical propagation of all uncertainties.

Given the measured abundances of the parent (^{187}Re) and daughter (^{187}Os) isotopes, each normalized to ^{188}Os , a stable isotope, the age and initial composition of the Os can be calculated from the basic age equation:

$$\left(\frac{^{187}\text{Os}}{^{188}\text{Os}}\right)_{\text{measured}} = \left(\frac{^{187}\text{Os}}{^{188}\text{Os}}\right)_{\text{initial}} + \left(\frac{^{187}\text{Re}}{^{188}\text{Os}}\right)_{\text{measured}} (e^{\lambda t} - 1) \quad (2)$$

where the measured ratios are determined from mass spectrometry, the initial ratio is the isotopic composition of Os at the time the sample equilibrated with and derived from its source, λ is the ^{187}Re decay constant, and t is the age of the sample in years. In any sample with measureable “common” Os (non-radiogenic Os incorporated into the sample when it formed), the initial Os isotopic composition of the common Os must be known. Thus there are two unknowns: the initial Os isotopic composition and the age. This is overcome by measuring multiple consanguineous samples and fitting a linear regression on an isochron diagram, a plot of the measured $^{187}\text{Re}/^{188}\text{Os}$ versus $^{187}\text{Os}/^{188}\text{Os}$ (Fig. 3).

Some samples have very little or effectively no common Os on formation. The mineral molybdenite (MoS_2), for example, takes in large amounts of parent Re, but almost quantitatively excludes Os at the time of crystallization. Other sulfides may also have unusually high $^{187}\text{Re}/^{188}\text{Os}$ ratios in the thousands or tens of thousands – so-called low-level highly radiogenic (LLHR) samples (Stein et al. 2000). In such cases, for which the Os is nearly 100 % radiogenic, the traditional isochron diagram is meaningless. Any presumed measurement of ^{188}Os clearly carries an extreme uncertainty (since there is too little to measure!). This is described in more detail below in the sections that describe dating molybdenite and LLHR samples.

Historical Background

The promise of highly accurate and precise Re–Os chronology was realized in the mid-1990s after four major, analytical issues were overcome: (1) lack of sensitive mass spectrometry techniques, (2) poor stoichiometry of Os standard materials, (3) difficulty equilibrating spike and sample Re and Os, and (4) uncertainty in the ^{187}Re decay constant. Resolving these issues opened the door to a wide

Fig. 3 Example of a Re–Os isochron plot. Four shale samples (or four related sulfide minerals), for example, were deposited at time zero, and all acquired Os from seawater with the same initial $^{187}\text{Os}/^{188}\text{Os}$ ratio. Over time, as ^{187}Re decays to ^{187}Os , the position of each point shifts up and to the right. The increase in $^{187}\text{Os}/^{188}\text{Os}$ is proportional to the magnitude of $^{187}\text{Re}/^{188}\text{Os}$ for each point. Linear regression of the four points at $t > 0$ yields a straight line with the equation shown. The slope ($m = e^{\lambda t} - 1$) is a function of the age of the sample and the decay constant. The y-intercept is the initial $^{187}\text{Os}/^{188}\text{Os}$ ratio, the ratio that would exist in a sample that had no parent ^{187}Re . The uncertainties on the slope and initial $^{187}\text{Os}/^{188}\text{Os}$ ratio depend on the analytical uncertainties for each data point and the goodness of fit (MSWDs, or mean square of weighted deviations) for the regression

range of applications for geologic problems from the mantle to the crust, from magmatic systems to surface processes.

Negative TIMS

Many isotopic methods rely on measurements of positive ions by thermal ionization mass spectrometry (TIMS). Recognition that both Re and Os are much more efficiently ionized as negative ions enabled far more precise measurements of Re and Os isotopic compositions on picogram quantities (Creaser et al. 1991; Völkening et al. 1991). The switch to negative TIMS (NTIMS) was critical to the development of Re–Os isotope geochemistry of crustal materials, as many labs turned to this new and more precise analytical tool. Analysis of Re isotopes by MC-ICP-MS has continued in some labs because it affords the opportunity to correct for instrumental mass fractionation of Re isotopes. In addition, a few labs have developed high-precision methods for analysis of Os isotopes by direct sparging of Os from the reaction vessel into an MC-ICP-MS (e.g., Hassler et al. 2000; Nozaki et al. 2012; Sen and Peucker-Ehrenbrink 2014).

Stoichiometry of Os Standards

Accurate concentration analyses using isotope dilution depend critically on the accuracy of the gravimetric standards used to calibrate spikes. The materials used to make Os standards are notoriously nonstoichiometric, leading to inherent errors in the calculated Os concentrations (Morgan et al. 1995). Alternative materials have been used to overcome this (Shen et al. 1996; Yin et al. 2001), but the inconsistencies remained. Selby and Creaser (2001) adapted an earlier method (Gilchrist 1932) to reduce ammonium hexachloroosmate to a pure osmium metal sponge

and thereby directly measure the Os content of the salt. A further adaptation of this method yields a robust measurement for the Os standard used today at AIRIE (Markey et al. 2007). Nevertheless, the persistent problem with stoichiometry of Os gravimetric standards remains challenging.

Spike Challenges: Equilibration Difficulties and the Mixed Re-double Os Spike

A long-standing challenge was achieving isotopic equilibrium between the sample and Os spike without loss of Os. Loss of Os is especially problematic for open-vessel methods or use of PTFE vessels, through which Os may diffuse. External precision (reproducibility) was greatly improved as laboratory methods moved from less reliable equilibration of spike and sample Re and Os by oxidizing alkaline fusion (Morgan and Walker 1989; Markey et al. 1998) to high-pressure and high-temperature sample dissolution and spike equilibration using inverse aqua regia in a sealed Carius tube (Shirey and Walker 1995).

A particular challenge with spiking is presented by samples with low concentrations of common Os and very high concentrations of radiogenic ^{187}Os . There are no well-measured ratios of Os isotopes that are neither radiogenic nor impacted by the addition of the spike. Thus, there is no mechanism for monitoring mass fractionation or determining the amount of common Os. These problems were resolved simultaneously with development of a mixed Re-double Os spike (^{185}Re – ^{188}Os – ^{190}Os ; Markey et al. 2003). Sufficient ^{188}Os spike is added to match the abundance of ^{187}Os , so that the $^{187}\text{Os}/^{188}\text{Os}$ ratio is well measured. In the same spike solution, a small amount of ^{190}Os is used to achieve a well-measured ratio with ^{192}Os , the most abundant isotope in the common Os spectrum. The well-determined $^{188}\text{Os}/^{190}\text{Os}$ ratio is used for the fractionation correction, while the balanced $^{190}\text{Os}/^{192}\text{Os}$ ratio is used to determine the amount of common Os in the sample. At the same time, use of a mixed Re–Os spike eliminates weighing errors associated with spike addition. This breakthrough has dramatically improved the precision and accuracy of Re–Os ages for young molybdenites and LLHR samples.

Half-Life Hurdles: The ^{187}Re Decay Constant

Establishing the half-life of a parent isotope with certainty is imperative for radiometric dating. Molybdenite, with its extraordinarily high Re concentrations and negligible common Os, contains essentially pure ^{187}Os , thereby providing the first reliable estimates of the half-life of ^{187}Re at about 43.5 b.y. (Herr and Merz 1955; Hirt et al. 1963).

Fifteen years later, the ^{187}Re half-life was determined at 45.6 ± 1.2 b.y. by assuming the slope of a meteorite isochron represented an age of 4.550 Ga (Luck and Allègre 1982). Re–Os ages for 11 molybdenites based on this revised half-life showed that, in a few cases, ages were too old (some older than the age of the earth). These highly inaccurate results were attributed to Re loss due to metamorphic and/or hydrothermal processes (Luck and Allègre 1982) – a major setback for Re–Os dating of molybdenite, as the chronometer was labeled as unreliable.

The half-life of ^{187}Re was again redetermined as 42.3 ± 1.3 Ga by measuring ingrowth of ^{187}Os over several years in a purified kilogram of Re (as perhenic acid, HReO_4 ; Lindner et al. 1989). Analysis of the same molybdenites that previously gave aberrant ages (Luck and Allègre 1982) now produced ages in good agreement with wall rock ages determined by other isotopic methods, leading to the conclusion that earlier discordant results reflected sample-spike equilibration problems rather than issues with the molybdenite chronometer (Suzuki et al. 1992, 1993).

The 3 % uncertainty on the ^{187}Re half-life determined by Lindner et al. (1989) placed serious limits on Re–Os geochronology. Two labs simultaneously undertook improvements by back-calculating the ^{187}Re decay constant from Re–Os isotope systematics in iron meteorites well dated by other methods. Shen et al. (1996) calculated a ^{187}Re decay constant of $1.66 \times 10^{-11} \text{ year}^{-1}$; while

they do not report an uncertainty for their decay constant, it is tied to the 1.2 % uncertainty on the calibration of their Os tracer. Smoliar et al. (1996) examined Re–Os systematics in group IIIA iron meteorites; by assuming these formed at the same time as angrite meteorites that yield a concordant Pb–Pb model age (Lugmair and Galer 1992), they were able to calculate the ^{187}Re decay constant at $(1.666 \pm 0.017) \times 10^{-11} \text{ year}^{-1}$. The assumption that the analyzed group IIIA and angrite meteorites are the same age is supported by agreement within $\pm 5 \text{ m.y.}$ of the ^{53}Mn – ^{53}Cr formation intervals. The $\pm 1.02 \%$ uncertainty calculated for the Smoliar et al. (1996) ^{187}Re decay constant can be reduced to $\pm 0.31 \%$ if the lab's Os standard can be tied back to the University of Maryland standard used by Smoliar et al. (1996).

Persistent Misperceptions

It is not about closure temperatures! Rather, it is the “container” that assures isotopic closure. The geochemical behavior of Re and Os controls the reliability of the Re–Os chronometers. Neither element is accommodated by silicate minerals, and neither element is soluble in reducing aqueous fluids. Thus, there are only two routes for either Re or Os to escape from its hosting phase: (1) sit adjacent to another phase with a comparable affinity for either Re or Os under conditions that allow diffusion or (2) interact with an oxidizing fluid. An isolated sulfide mineral surrounded by silicates will not lose Re or Os. Surface weathering or attack by any oxidizing fluid, in contrast, promotes disturbance of the Re–Os isotopic system (e.g., Georgiev et al. 2012).

A “Model 1” isochron does not mean “precise and accurate”! Many labs plot isochrons from their data using the freely available software Isoplot (Ludwig 2012). The first model for linear regression used by Isoplot is termed “Model 1” and assumes that scatter of data from the straight line is attributable only to the uncertainties of the individual data points (following York 1969). The program also calculates a “probability of fit” and rejects the Model 1 regression if the probability is $< 15 \%$. (The user may change this value to any probability between 5 % and 30 %.) If the Model 1 regression is rejected, Isoplot calculates a “Model 3” age, which assumes an unknown, but normally distributed variation in the initial $^{187}\text{Os}/^{188}\text{Os}$ ratio. This change in regression model results in a larger age uncertainty. In fact, the size of the uncertainties for individual data points strongly impacts the choice of model – the larger the uncertainties, the higher the probability of fit, and therefore, the greater likelihood that the Model 1 fit will be accepted. Thus, “better” data – that is, more precise analyses and/or underestimated analytical uncertainties – are less likely to result in a Model 1 regression. Conversely, less precise measurements and/or overestimated analytical uncertainties for each data point readily result in an unwarranted Model 1 regression. Examples of improbably high analytical uncertainties and overly optimistic isochrons are all too common.

A lower MSWD does not always mean a better isochron! Ludwig (2012, footnote on p. 22) eloquently states the meaning of “MSWD”:

MSWD = Mean Square of Weighted Deviates. This does not refer to porcine pervers; it is, roughly, a measure of the ratio of the *observed* scatter of the points (from the best-fit line) to the *expected* scatter (from the assigned errors and error correlations). *The MSWD parameter cannot be compared to the classical R^2 parameter, and is not a measure of how highly correlated the X- and Y-values are.* If the assigned errors are the only cause of scatter, the MSWD will tend to be near unity. MSWD values much greater than unity generally indicate either underestimated analytical errors, or the presence of non-analytical scatter. MSWD values much less than unity generally indicate either overestimated analytical errors or unrecognized error-correlations.

In short, a low MSWD may result from an overestimation of analytical uncertainties. Equally important, an $\text{MSWD} \ll 1$ suggests that analytical uncertainties have been underestimated – though it can also indicate an extraordinarily colinear data set. Ideally, for a precise isochron based on good measurements of well-behaved samples, the MSWD will be close to 1.

Applications

The many improvements made during the 1990s for analytical methods and standards opened a world of new applications for Re–Os geochronology. Precision and accuracy of measurements of meteoritic material and mantle xenoliths greatly increased. With the Smoliar et al. (1996) ^{187}Re decay constant, the first NTIMS analyses of molybdenites aligned with U–Pb ages for related zircons (Stein et al. 1997, 2001). High-precision and accurate analyses of low-level basalts, crustal sulfides, and organic matter became a reality. The next sections provide an overview of these applications, each of which is also discussed in separate focused and condensed chapters in this volume. Here we pay particular tribute to the development and application of the Re–Os molybdenite chronometer, as its value is no less than that of zircon dating.

Meteorites and Mantle

Much of the early work on Re–Os systematics in earth materials focused on xenoliths from the earth's mantle and on meteorites (see also entry “► [Meteorites \(Re–Os\)](#)”). Prior to the 1990s, analytical limitations required the use of materials with relatively high concentrations of Re and Os. More importantly, the strong fractionation of both Re between earth's mantle and mantle-derived partial melts, and of both Re and Os between silicates and metals, affords ample opportunities to explore the origins of planetary bodies and the evolution of planetary interiors. Re–Os systematics can reveal the age and probable origin of meteorites from the solar nebula, the formation of Fe–Ni cores, and timing of secondary alteration (cf. Walker, this volume). Studies focused on shergottite meteorites, of Martian origin, reveal the evolution of the Martian mantle, early magma ocean, and late accretion (e.g., Brandon et al. 2012).

Re–Os isotopic studies of mantle xenoliths, exposed mantle peridotites, and mantle-derived basalts provide high-quality information on melt-depletion events in the mantle, the evolution of the mantle through time, and the preservation of subcontinental mantle lithosphere. Reisberg et al. (2004) provide an example of multiple processes impacting Os isotope composition of mantle samples preserved as xenoliths, deriving useful model ages for melt extraction, yet questioning the interpretation of these data as mantle stabilization ages. Rudnick and Walker (2009) give an excellent review of the fundamentals, potential pitfalls, and lessons learned in two decades of Re–Os applications in the mantle.

Crustal Sulfides

Molybdenite Geochronology

Molybdenum disulfide (MoS_2) or molybdenite is a silver-colored mineral with a distinct bluish tint. The blue tint is particularly notable in samples with high Re. This hexagonal (rarely trigonal) mineral is soft, has a distinct platy cleavage, and can easily be bent with the fingers (Fig. 4). Molybdenite occupies a unique niche – it is the only naturally occurring mineral that takes in significant Re, usually at the level of tens to hundreds of ppm, other than its exceedingly rare Re-rich solid-solution cousin, rehiite (ReS_2 ; Korzhinsky et al. 2004; Tessalina et al. 2008). Molybdenite occurs in a wide range of geologic environments. Almost invariably, it is present in porphyry-style ore deposits worldwide. It may also be found as a minor accessory mineral in silicic-felsic metamorphic rocks and biotite gneisses. Molybdenite is most commonly associated with quartz veins or as disseminated blades or rosettes in felsic magmatic-metamorphic rocks (Fig. 5). The ability to directly date molybdenite gave the economic geology community accurate and precise ages for a wide array of ore deposits and gave the geologic community direct ages for sulfide occurrences in the earth's crust (Stein et al. 2001; cf. review in Stein 2014).

Fig. 4 Molybdenite crystals from Råde, Norway, illustrate hexagonal form and platy texture. This exceptional specimen is about 6 cm across and belongs to the Natural History Museum in Oslo. Crystals as large as 15 cm in diameter have been reported from Råde (Photo by H. Stein)

Fig. 5 (a) Quartz-molybdenite veins in the Primos rhyolite porphyry, Henderson Mo porphyry deposit, Colorado. Field of view is 10 cm across. (b) Banded quartz-molybdenite vein cutting fine-grained biotite hornfels, Myszków Mo deposit, Poland. Thumb and forefinger to right, pencil tip to left for scale. Sample is wet to enhance contrast. (c) Porphyritic granite with disseminated molybdenite and minor finely disseminated chalcopyrite (*bottom center*) from the Myszków Mo deposit, Poland. Two drill pits (*inside yellow circle*) show how molybdenite is excavated for Re–Os dating. Pencil tip for scale. Sample is wet to enhance contrast (Photos by H. Stein)

Uniquely, molybdenite has very high Re/Os ratios on crystallization (generally $>10^6$) and takes in essentially no common (i.e., initial) Os. If common Os is present in the sulfide-depositing fluid, it is accommodated by other co-crystallizing sulfides. With vanishingly low common Os (and therefore, no initial ^{187}Os) in molybdenite, the decay equation for calculating a molybdenite age is elegant in its simplicity:

$$^{187}\text{Os}_{\text{measured}} = ^{187}\text{Os}_{\text{initial}} + ^{187}\text{Re}_{\text{measured}}(e^{\lambda t} - 1) \quad (3)$$

reduces to

$$^{187}\text{Os}_{\text{measured}} = ^{187}\text{Re}_{\text{measured}}(e^{\lambda t} - 1) \quad (4)$$

Here the model age (t), reflecting the time of crystallization, is the only unknown. The age is therefore readily determined from a single sample of molybdenite. Lambda (λ) is the ^{187}Re decay constant.

The ^{187}Re – ^{187}Os radiometric clock held in the mineral molybdenite was explored in earnest in the 1960s (Hirt et al. 1963; Herr et al. 1967). Analytical issues and a poorly determined ^{187}Re decay

constant stalled progress. In the 1990s, early pioneering work in ^{187}Re – ^{187}Os dating of molybdenite was carried out by Du Andao, a Chinese chemist, who early on realized the potential of the method for this mineral (Du et al. 1995). Her lab quickly became a venue for many Chinese geologists to simply acquire dates from her for Chinese ore deposits, and a hailstorm of papers reporting molybdenite ages ensued. These geologists depended on her meticulous work and laboratory results. Also in the 1990s, another chemist, Katsuhiko Suzuki, was independently exploring molybdenite as a geochronometer in Japan. His lab became a focal point for mixing geologists and geochemists to jointly tackle geologic problems with Re–Os isotope geochemistry. In the early 1990s, both Drs. Du and Suzuki were limited by the analytical capability offered by ICP-MS (Inductively Coupled Plasma Mass Spectrometry) prior to the advent of multi-collector instruments.

Other groups were also limited by ICP-MS instrumentation and by assessing the accuracy of ^{187}Re – ^{187}Os molybdenite ages through their agreement with K–Ar ages (e.g., McCandless and Ruiz 1993). It soon became clear that primary ages in the ore-forming environment were held by molybdenite and not by traditionally dated ore-associated gangue minerals (e.g., alunite and sericite), for which argon-based dating had been employed (Suzuki et al. 1996; Watanabe and Stein 2000; Stein et al. 2001; Selby et al. 2002).

The ages achieved by early workers, nonetheless, were encouraging. But a breakthrough in analytical technology was needed. This was delivered with NTIMS (Negative Thermal Ionization Mass Spectrometry), as two working groups realized that Re and Os could be measured as negative ions (Creaser et al. 1991; Völkening et al. 1991). This analytical breakthrough was immediately utilized to successfully develop the ^{187}Re – ^{187}Os chronometer in molybdenite, achieving accurate ages at high precision (Stein et al. 1997; Markey et al. 1998).

In addition to analytical challenges, a limiting factor in putting the molybdenite chronometer to use was the accurate determination of the ^{187}Re decay constant and its uncertainty. Ultimately, the ^{187}Re decay constant of Smoliar et al. (1996) became the established value and is the most widely used today. More recent attempts to further revise the ^{187}Re decay constant by pairing up molybdenite Re–Os and zircon U–Pb ages from the literature (Selby et al. 2007a) rely on two geologic assumptions: (1) molybdenite and zircon formation are contemporaneous, and implicit to the first assumption, (2) there is only one generation of molybdenite and one episode of zircon formation at a locality. In hindsight, geologic reason tells us this assumption is flawed; when multiple dates are available, molybdenite (and zircon) generally shows a range of ages at a single locality. The cleanest data sets are from porphyry-style deposits, but these also may have extended durations (e.g., Los Pelambres, Chile; Stein 2014). Therefore, the ^{187}Re decay constant that ties back to the meteorite community is best used; the complexities of crustal rocks do not lend themselves well to establishing decay constants.

Still other vexing issues lay ahead before ^{187}Re – ^{187}Os dating of molybdenite would become mainstream geochronology. Recognition of parent-daughter (^{187}Re – ^{187}Os) decoupling within molybdenite crystals presented a new challenge (Stein et al. 2001). Qualitative trial-and-error studies with different grain sizes, different crystals (chopped with a razor, peeled along cleavage planes, or powdered by drilling), different occurrences, and different milligram quantities of molybdenite revealed that geologic sense, not quantity, of molybdenite should drive the sampling. If part of a crystal is sampled, then the whole crystal must be sampled to ensure that all of the parent and daughter are included in the analysis. In fact, acquisition of the molybdenite mineral separate in a geologically meaningful context is the most critical step for molybdenite dating (Stein et al. 2001; Stein 2006, 2014). Unlike the approach for zircon U–Pb dating, whole-rock crushing to acquire a vial of molybdenite grains puts Re–Os dating at risk. If more than one generation of molybdenite is present, even if closely spaced in time, this approach yields variable ages that cannot be well

reproduced. In the same way, if decoupling is present at the scale of the sampling, ages will be variable and cannot be well reproduced. *It is the inability to replicate an age from the same separate that signals decoupling.* The decoupling of ^{187}Re – ^{187}Os in molybdenite is generally greater in coarser-grained samples, in older high-Re molybdenites that have accumulated significant radiogenic ^{187}Os , and in deformed molybdenites (Stein et al. 2003). Simply put, the accumulated radiogenic Os is desperate to get comfortable in the molybdenite structure and, at any opportunity, will migrate to crystal defects or dislocations (Stein et al. 2003). The early empirical recognition of parent-daughter decoupling was later verified through LA-ICP-MS of molybdenite (Stein et al. 2003; Selby and Creaser 2004). Thus, laser ablation technology cannot be used for ^{187}Re – ^{187}Os molybdenite dating (e.g., Košler et al. 2003). A subsequent atomic level study confirmed the suspected mobility of radiogenic Os within the molybdenite structure (Takahashi et al. 2007).

A unique aspect of ^{187}Re – ^{187}Os dating of molybdenite is that this sulfide rarely forms overgrowths (Stein et al. 2004; Aleinikoff et al. 2012). This is not the case for other sulfides; for example, pyrite is notorious for overgrowths. Without the complexity of overgrowths, this makes working with molybdenite far simpler than deciphering some U–Pb histories in zircon and monazite. Another positive feature is that the molybdenite chronometer remains intact, even at granulite facies temperatures (e.g., Bingen and Stein 2003). Compromise of the ^{187}Re – ^{187}Os clock in molybdenite should not be associated with temperature, but with chemical stability of sulfide (i.e., oxidation; cf. discussion in Stein 2014).

In nature, however, there are always exceptions when things at first seem simple. Though rare, a small population of molybdenites began to show up with measurable common Os. Not surprisingly, these molybdenites generally occur in the absence of other sulfides that accommodate Os, a platinum group element (PGE), in their structures. Silicate minerals typically do not substitute Os in their structures, so in such circumstances this left molybdenite vulnerable to squeezing Os into its structure. This reality led to the development of a mixed Re-double Os spike, now widely in use, for analyzing molybdenite (Markey et al. 2003). The concept is simple: a single spike solution contains enriched ^{185}Re – ^{188}Os – ^{190}Os . The ^{185}Re is used to determine the parent ^{187}Re concentration in a molybdenite sample, as there are only two isotopes of Re. The ^{188}Os in the spike solution is used to precisely determine the radiogenic ^{187}Os , just one amu (atomic mass unit) away, and the ^{190}Os is used to determine the ^{192}Os (the most abundant common Os mass). From these measurements, the total Re and Os concentrations in the sample can be reconstructed, and the dating is atomically accurate. Further, the double Os spike eliminates weighing errors for single Re and Os spike solutions and permits a mass fractionation correction for Os (Markey et al. 2003).

A new technology requires a reference material that can be accessed by multiple labs and used for interlaboratory comparison. Early workers used a well-homogenized, milled molybdenite powder from the Huanglongpu Mo deposit in China to assess internal (within lab) and external (between labs) repeatability of age results (Stein et al. 1997; Selby and Creaser 2001; Du et al. 2004). From this, the concept of a molybdenite isochron was derived, with the regression line defined by coupled variation in ^{187}Re and ^{187}Os concentrations and projecting to an intercept of zero initial ^{187}Os (Stein et al. 1997). Subsequently, a milled molybdenite powder from the Henderson mine in Colorado was characterized as a reference material (Markey et al. 2007). Molybdenite from this particular porphyry Mo deposit was specifically chosen for three reasons: (1) undeformed, minimizing decoupling issues, (2) relatively low Re, and (3) young age (27.656 ± 0.022 Ma), limiting the amount of ^{187}Os introduced as a possible lab contaminant. The Henderson molybdenite was endorsed by NIST (RM#8599) and can be purchased through NIST as a reference material for ^{187}Re – ^{187}Os age determinations. Importantly, RM#8599 is not a reference material for Re and ^{187}Os

concentrations, only for the accuracy of ^{187}Re – ^{187}Os ages. The Re and ^{187}Os concentrations vary, but are perfectly coupled such that the age is highly reproducible (Markey et al. 2007).

While dating ore deposits was the original motivation and a primary application for molybdenite dating, the mineral's widespread occurrence as an accessory phase provides additional opportunities. Molybdenite crystallization can be tied to specific tectonic events, yielding timing, for example, of fluid-flow events during metamorphism (Stein 2006), specific deformation events (Stein and Bingen 2002), and progressive and episodic extensional tectonism (Zimmerman et al. 2008).

In sum, molybdenite presents the geologic community with a simple, yet elegant, radiometric clock through ^{187}Re – ^{187}Os . What was novel turned mainstream with NTIMS, the use of a double Os spike, and a certified reference material for the community. Depending on Re concentration in the molybdenite, the chronometer can accommodate samples from Early Archean to well less than 1 Ma. Potential decoupling can be overcome with sensible sampling and thoughtful mineral separation. For a detailed review of molybdenite and sulfide geochronology, rich in examples, consult Stein (2014).

In this brief section, we have focused on the steps leading to breakthroughs and the hurdles in establishing the ^{187}Re – ^{187}Os chronometer for this unassuming, soft, pliable, and isotopically strong mineral.

LLHR (Low-Level Highly Radiogenic) Sulfides

The LLHR term was introduced to describe samples with molybdenite-like Os isotopic compositions but with much lower Re concentrations, at the ppb or even ppt level (Stein et al. 2000). That is, the common Os is low enough relative to the radiogenic ^{187}Os that single samples may provide accurate and precise ^{187}Re – ^{187}Os ages. The principles are the same as described for molybdenite, with the caveat that the blank correction may be important. The key equation for dating is therefore Eq. 4 (above).

Arsenopyrite (FeAsS) and some pyrites (FeS_2) may be LLHR. Because arsenopyrite and pyrite are commonly associated with Au, these two sulfides are sought out for dating gold deposits when molybdenite is absent from the sulfide assemblage. Like molybdenite, arsenopyrite and pyrite may permit ^{187}Re – ^{187}Os dating of ore deposits. Further, pyrite is the most common sulfide in the earth's crust, so this mineral has additional value for Re–Os geochronology in general. If sulfides, including arsenopyrite and pyrite, have significant common Os, they can still be dated using the traditional $^{187}\text{Re}/^{188}\text{Os}$ versus $^{187}\text{Os}/^{188}\text{Os}$ isochron approach, but this requires analyses of multiple contemporaneously formed samples. For further discussion of LLHR samples, refer to Stein (2014). Several key studies brought attention to arsenopyrite as a valuable sulfide for Re–Os dating (Arne et al. 2001; Bierlein et al. 2006; Morelli et al. 2005, 2007, 2010). In addition, Morelli et al. (2010) showed that the Re–Os systematics in arsenopyrite were intact, even at temperature $>400^\circ\text{C}$. Although unusual, even pyrrhotite can be LLHR, yielding primary ages if the sample does not include other sulfides (Demaiffe et al. 2013).

Dating Shales: Source Rocks for Oil

The Re–Os budget held in crustal rocks is dominated by shales (Fig. 1). Groundbreaking Re–Os work on dating shales relied on whole-rock analyses of organic-rich shales (e.g., Ravizza and Turekian 1989; Creaser et al. 2002). Subsequently, Hannah et al. (2004) made use of syn-sedimentary pyrite with remarkable success on samples of Paleoproterozoic age ($2,316 \pm 7$ Ma). The field of Re–Os geochronology quickly expanded to include dating of the organic (hydrogenous) component of organic-rich shales isolated from the clastic or detrital component of the shale (e.g., Selby and Creaser 2003, 2005a; Kendall et al. 2009; Yang et al. 2009). Re and Os concentrations in the organic

component are easily in the ppb range. The technique soon became well established as a tool to place age pins in the stratigraphic column for geologic time scale calibration. Previously, only U–Pb zircon ages on ash beds had prevailed as absolute time markers in sedimentary sections. Absolute time is also a valuable commodity for correlations where provincial species could not be used to link widely separated paleogeographic terranes (e.g., Xu et al. 2009).

The newfound ability to date shales led quickly to dating key units associated with major earth events; this can help resolve debates over the reach of these events in time and space – whether global or regional, abrupt or protracted. For example, localities with shale records associated with Neoproterozoic glaciation and the theory of a frozen snowball earth could now be time-bracketed with Re–Os dating of shales (e.g., Kendall et al. 2004, 2006, 2013; Rooney et al. 2010, 2011). Other earth events such as biotic crises associated with mass extinctions or major faunal turnovers provide excellent venues for Re–Os dating, as widespread anoxia preserved vast areas of organic material intact with their trace metal record of toxic seawater (e.g., Turgeon and Creaser 2008; Selby et al. 2009; Georgiev et al. 2011; Xu et al. 2014).

Since organic-rich black shales are potential source rocks for hydrocarbons, the petroleum industry became immediately interested in using the method not only as a measure of absolute time but as a correlation tool across basins, continents, and hemispheres. Good isochron regressions define initial $^{187}\text{Os}/^{188}\text{Os}$ ratios for paleo-seawater, useful measures for what was entering, mixing with, and characterizing the Re–Os budget of oceans on a more global scale (see Fig. 8). Simplistically summarized, the marine geochemical record, including Re–Os chemistry, is transferred to black shales on the seabed. During periods in earth history when the whole of seawater may have been anoxic, including the photic zone (e.g., Grice et al. 2005), the connection between top and bottom is profound. A more stratified ocean with variable oxygenation presents a more complex architecture linking the photic zone and seabed. This scenario holds for anoxic-euxinic waters in lacustrine sediments as well. With adequate ventilation and mixing, the seawater (lake water) Os isotope ratio represents the balance of (1) continental erosion (intimately linked to continental uplift) and (2) hydrothermal input. *Continental erosion* at a particular time in earth history reflects the kinds of rocks that are dominating the erosional cycle, that is, what rivers are delivering to seas. *Hydrothermal input* at a particular time in earth history may be dominated by mafic magmatism penetrating the seabed or terrestrial volcanic systems belching aerosols and particulate matter that ultimately mix at the seawater interface where they may incite algal blooms or otherwise feed microorganisms in the photic zone. While the notion of a global seawater Os isotopic composition is a tidy concept, it soon became apparent that restricted basins and isolated water masses, both horizontally and vertically, both locally and widespread, have the potential to harbor Os isotopic compositions that deviate from an assigned global Os isotopic value. Nevertheless, the concept of a variable Os isotopic composition for seawater through time works well, and the short residency time for Os in seawater gives us an increasingly tuned record of past earth events at high resolution (see Fig. 8).

As discussed throughout this contribution, the Re–Os data are governed by geologically responsible sampling. Drill core samples are highly preferred to outcrop samples to eliminate the possibility of disturbed isotope systematics related to weathering (Georgiev et al. 2012). At a minimum, flawed sampling at the outset compromises results and, more seriously, may disguise potentially meaningful results. Since we do not know the rate of sedimentation, proper sampling of shale means that the smallest possible interval, *but representative*, should be taken. After this interval is powdered, an aliquot of several hundred milligrams is removed for the Re–Os analysis. Sampling too large a stratigraphic interval risks capturing too large an interval of time – this compromises isochroneity and risks reducing the spread of the data points for a statistically well-constrained

isochron regression. Sampling too small a stratigraphic interval risks capture of postdepositional, small-scale isotopic exchange – for example, exchange among organic particles and sulfides after pore waters have been isolated from the overlying water column or redistribution of sediment by burrowing organisms.

What does this mean for Re–Os shale chronology? First, there is no threshold value for the amount of shale to be acquired, pulverized, and homogenized; each interval of core requires its own sampling strategy. Ideally, an isochron is derived from 5 to 8 samples, taken from 20 to 30 cm of core (Fig. 6). Sampling for an isochron should not be carried out over many meters or tens of meters of section. *Generally* speaking, for 20–30 stratigraphic centimeters of section and for ideal, well-laminated black shales without bioturbation, <30 g of pulverized shale sample (i.e., <1 cm stratigraphic span) routinely provides good ages (Fig. 7 and discussion in caption). Again, these are *generalized* parameters, and the sample stratagem depends on depositional rates, stability of the initial Os ratio, and Re/Os ratios in the shale samples. Shales with lower Re require larger aliquots for the analyses, but not necessarily larger bites of the stratigraphic section for homogenization.

Os Isotope Seawater Curve

The Os isotopic composition of the oceans has varied through time because of changes in the balance among the various Os sources, especially inputs from continental weathering (e.g., Peucker-Ehrenbrink and Ravizza 2000) and the several mechanisms for acquiring chondritic Os. Organic-rich sedimentary rocks, especially black shales, hold a record of ancient seawater Os isotopic composition. By far the best evidence that a sedimentary section has remained closed to Os gain, loss, or isotopic exchange is a suite of samples that form a precise isochron. In the last two decades, since high-precision Re–Os geochronology became a reality, a growing archive of initial $^{187}\text{Os}/^{188}\text{Os}$ ratios and corresponding ages has been acquired from isochrons. Figure 8 shows a plot of seawater $^{187}\text{Os}/^{188}\text{Os}$ versus age; for comparison, the Sr isotope seawater curve (Howarth and McArthur 1997; McArthur et al. 2001; Shields 2007) is plotted on the same figure. The well-known Sr isotope curve reflects four decades of effort; the Os isotope curve is in its early stages, with much still to be developed. In addition to these data, a number of studies have generated calculated initial $^{187}\text{Os}/^{188}\text{Os}$ ratios, derived from Re–Os isotopic ratios and a known (or assumed) age (e.g., Peucker-Ehrenbrink et al. 1995). Although a closed isotopic system is not proven, many of these data are likely valid, especially for young samples, and the effect of outliers tends to be swamped by the sheer volume of data. Studies based solely on calculated initial $^{187}\text{Os}/^{188}\text{Os}$ ratios have effectively illustrated, for example, the effect of a bolide impact at the Cretaceous-Paleogene boundary (Peucker-Ehrenbrink et al. 1995).

Figure 8 reveals a striking difference between the Sr and Os isotope seawater curves: the Os curve is spiky, with sharp highs and lows; the Sr curve is smooth, with more subdued variations. This is a simple result of the relatively long residence time for Sr in the oceans (~2 m.y.; McArthur et al. 2000) and the comparatively short residence time for Os (~28,000 years, Georg et al. 2013; still controversial, Paquay and Ravizza 2012). Short-term effects, such as bolide impacts or inputs from large igneous provinces, readily deflect the Os curve but are washed out by the long residence and mixing of Sr isotopes in seawater. A second critical difference is the continual buildup of Re and thus radiogenic Os in the crust. Neither element was mobilized in surface environments under earth's anoxic Archean atmosphere (Hannah et al. 2004), but both have accumulated since then, sequestered in large amounts in organic-rich sedimentary rocks. While both the Sr and Os seawater curves reflect variable input from continental weathering, Os is strongly controlled by the proportion of organic-rich sedimentary rocks undergoing weathering (Georgiev et al. 2012), whereas the Sr isotope

Fig. 6 Sampling shales is the most critical step for Re–Os dating. Drill core showing organic-rich Jurassic *black shale* from Svalbard. The sampling strategy illustrated here is that used by the AIRIE Program. Re–Os analysis of an aliquot from a shale sample acquired from within each *green rectangle* is very likely to yield an accurate and precise isochron age. This particular interval will provide direct age constraints for the Boreal ammonite, *A. subkitchini*

balance is controlled by weathering of carbonates and silicates (Ravizza 2007). The two systems provide complementary data for deducing causes of changes in marine chemistry through time.

Hydrocarbons: What Are We “Dating”?

The proven concentration of Re and Os in organic matter incites immediate interest in the potential for directly “dating” hydrocarbons. Simple thought experiments, however, draw immediate doubts: hydrocarbon systems are by definition open systems. Hydrocarbons are generated by maturation of organic material in a source rock, are expelled, migrate, and may eventually accumulate in a porous reservoir rock with an adequate seal. At what point might Re–Os systematics reveal useful information? How can we know which processes are elucidated by those systematics?

The first attempted Re–Os measurements on organic matter focused on physically separated organic detritus and associated pyrite in the Upper Jurassic Morrison formation (Hannah et al. 2000; Hannah and Stein 2003). All samples yielded high, readily measured concentrations of both Re and Os, with Os and especially Re enriched in organic matter relative to pyrite. Although some useful information could be extracted from closely spaced samples, an approach that subsequently proved useful for dating shales, most of the section was disturbed by open-system behavior. The organic detritus served as a sink for Re and Os dissolved in oxidizing groundwater that flowed through the Morrison sandstones for tens of millions of years.

The first breakthrough was a study by Selby and Creaser (2005b). They analyzed widely spaced samples from the extensive oil sand deposits of Alberta, Canada. A subset of their Re–Os data pointed to an age of 112 ± 5.3 Ma, interpreted as the petroleum emplacement age, and ruling out models suggesting Late Cretaceous hydrocarbon maturation and migration. The conclusions assume that the deposits spanning more than 400 km formed from the same source at the same time, a

Fig. 7 Sampling shales is the first critical step in Re–Os dating. Three intervals from a drill core, Jurassic black shale, Svalbard. CT images on *top* are paired with corresponding photo of the same drill core piece below. All samples are positioned stratigraphically up toward the top of the page. Cores are 5 cm in diameter. **(a)** IDEAL for Re–Os dating. Beautifully laminated organic-rich black shale with lighter, less organic-rich, siltier intervals visible. **(b)**. SUITABLE for Re–Os dating. Laminated black shale with brachiopod shells concave up indicating settling in quiet water; disseminated bright points are pyritized foraminifera indicating anoxic-euxinic conditions in the water column and bottom waters. **(c)** LESS DESIRABLE for Re–Os dating. Organic-rich black shale shows a myriad of fossil burrows, a record of intense bioturbation. As the organisms work their way into and out of the soft sediment bed, any variation in the osmium isotope composition is stirred at the mm to cm scale. With slow sedimentation rates, this has the potential to introduce scatter into an isochron (Samples collected and imaged by H. Stein and Ø. Hammer)

hypothesis supported by distinctive organic geochemistry. A concern is that 9 outliers of the 26 analyses were excluded on the basis of model initial Os ratios – statistically the same as removing any points not lying close to the isochron derived from all data. In addition, the preferred age was partly controlled by a single analysis (out of five) for one unusual deposit. Nevertheless, their landmark effort constituted a significant advance in analytical techniques and demonstrated that useful age information could be extracted from migrated hydrocarbons.

Fig. 8 Variations in the $^{187}\text{Os}/^{188}\text{Os}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ ratios in seawater through time. Inset shows the Phanerozoic with an expanded scale. The Os isotope curve shows only initial ratios from isochrons (see discussion in text). The Phanerozoic Sr seawater curve is from Howarth and McArthur (1997) and McArthur et al. (2001); the Precambrian Sr curve is from Shields (2007). The Os curve was compiled by the AIRIE Program from the literature and unpublished data

Subsequent work has documented Re–Os systematics in several hydrocarbon systems, both marine (e.g., Finlay et al. 2011; Lillis and Selby 2013; Hannah et al. 2014) and lacustrine (Cumming et al. 2014). Moreover, geologically reasonable ages for hydrocarbon maturation/expulsion tied to tectonism have been extracted from shales (Stein et al. 2012). Comparison of asphaltene and maltene fractions of individual crude oils (Selby et al. 2007b) and hydrous pyrolysis experiments (artificial hydrocarbon maturation; Rooney et al. 2012) both document minimal differences in both $^{187}\text{Re}/^{188}\text{Os}$ and $^{187}\text{Os}/^{188}\text{Os}$ between source rock and extracted oil and among hydrocarbon fractions. Unfortunately, the oil generated by hydrous pyrolysis did not contain measurable Re or Os and was not able to fully replicate natural processes (Rooney et al. 2012). Nevertheless, these studies affirm early work that shows little or no disturbance of Re–Os systematics in organic-rich sedimentary rocks upon hydrocarbon maturation (Creaser et al. 2002 and many subsequent papers on shale geochronology).

A major challenge for deriving age information from oils is generating a spread in $^{187}\text{Re}/^{188}\text{Os}$ from different components of a single oil. Without this, a statistically significant linear regression cannot be achieved, and thus the age and initial $^{187}\text{Os}/^{188}\text{Os}$ cannot be well determined. Selby et al. (2007b) showed that Re and Os are concentrated in the asphaltene fraction, Mahdaoui et al. (2013) further separated asphaltenes by sequential precipitation into strongly and weakly polar fractions. Her results further support observations that separation of lighter oils from asphaltenes does not significantly fractionate Re/Os or $^{187}\text{Os}/^{188}\text{Os}$, but a method is still needed for inducing a spread in Re/Os from a single oil sample. Notably, however, Ni and V concentrations peaked in mid-polarity fractions, while Re and Os dropped continuously from most to least polar. This argues against the commonly held assumption that Re and Os, like Ni and V, are bound in metalloporphyrins.

Re–Os analysis of oils is challenging and very much in its infancy. The potential to place time constraints on maturation, expulsion, and migration of hydrocarbons remains a powerful driver of research.

Summary and Challenges Going Forward

Re–Os geochronology can be used to date earth materials (e.g., sulfides, shales, oils) previously undatable by other isotopic methods. Of pivotal importance, these materials are directly linked to natural resources, both minerals and hydrocarbon, critical to human civilization.

For the immediate future, the challenge is no longer analytical, but geologic. We need to put forward bright and innovative thinking, with the basis for that thinking no longer tied to traditional models, but pointed toward new understanding of how earth's resources are ultimately generated. Re–Os offers more than geochronology. Acquiring an age for an ore deposit, or shale, gives us the last step in a long process. We have the data in hand to start thinking about “how it came about.”

Questions for the future must probe deeper than they have in the past. How can Re–Os be used to link the nascent beginnings of resource formation to the end product that is mined or drained from the earth's crust for profit? This is not esoteric information, but needed information for responsible exploration in the next century. What conditions, far and wide, deep and shallow, make it possible to liberate metals and hydrocarbons? This is part of the slippery question of source – where and how does it start? Our thinking should not be limited to the lithosphere and hydrosphere, but must include atmospheric processes. These three spheres collectively govern resources. Not surprisingly, they also govern the timely issue of climate change.

As a first next step and an easy one to take, reconciling seemingly disparate and non-isochronous data is a good place to start new thinking. There is no such thing as bad data; there is only complexity in data sets that should challenge our imaginations, not prompt us to look only toward the easily interpreted data sets. The barrage of analytical data in the last decade should drive new and thoughtful sampling with different questions in hand.

Clays and Glauconites (K–Ar/Ar–Ar)

Horst Zwingmann*

CSIRO Earth Science and Resource Engineering, Australian Resources Research Centre, Perth, WA, Australia
School of Earth and Environment, The University of Western Australia, Crawley, WA, Australia
Department of Applied Geology, Curtin University, Bentley, WA, Australia

Introduction

Both conventional K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating methods can be applied to clay minerals. Clay minerals are sheet silicates characterized by their small grain size ($<2\ \mu\text{m}$), thus requiring specialized separation and analytical methods for isotopic dating. Detailed accounts of the conventional K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating technique have been described by Dalrymple and Lanphere (1969), Faure (1986), Dickin (1995), McDougall and Harrison (1999), and Kelley (2002). The ages of clay minerals can be determined by measuring the amount of the argon isotope ^{40}Ar relative to the potassium content. ^{40}Ar is produced by the radioactive decay of the potassium isotope ^{40}K . Minerals generally contain negligible amounts of argon when they are formed, although small amounts of atmospheric argon may adhere to samples, which can be corrected for by using the known atmospheric $^{40}\text{Ar}/^{39}\text{Ar}$ ratio of 295.5 (Steiger and Jäger 1977). Thus, by measuring the ratio of ^{40}Ar to ^{40}K , and knowing the decay rate of ^{40}K , it is possible to calculate the time since the clay mineral formed.

What Are Clays?

Clay minerals are phyllosilicates; a comprehensive summary of their properties and genesis has been compiled by Srodón and Eberl (1984), Velde (1992), and Meunier (2005). Two clay minerals groups, illite and glauconite, can be dated using isotopic methods. Illite is a general term for a 10 angstrom ($\text{\AA}$) potassium dioctahedral mica-like clay mineral common in sedimentary rocks such as shales and sandstones. Glauconite is an iron potassium phyllosilicate mineral of characteristic green color that occurs in sandstone and carbonate-rich sedimentary rocks (Velde 2004).

As a generalization, illite and glauconite group clays have a dioctahedral mineral structure: $\text{K}(\text{Mg}, \text{Fe}, \text{Al})_2(\text{Si}, \text{Al})_4\text{O}_{10}$, with illite containing $\text{K} < 0.9 (\text{Al})$, and glauconite characterized by the presence of Fe with $\text{K} < 0.9 (\text{Al}, \text{Fe}, \text{Mg})$.

Clay minerals occur in different geological environments as both detrital and authigenic phases. One of the main challenges in clay geochronology is the separation of, and differentiation between, authigenic and detrital mineral phases that is necessary to obtain meaningful geological ages.

Why Date Clays?

Clay minerals are widespread in a variety of geological environments and their occurrence manifests numerous important processes throughout Earth history. Due to their capacity to swell and

*Email: horst.zwingmann@csiro.au

incorporate water, clay minerals are considered important in the evolution of life (i.e., Hashizume 2012). They form significant economic reservoir rocks for water and energy resources (Nadeau 2011). Glauconite is a common authigenic sedimentary mineral and has been used to constrain the geological timescale where biostratigraphic control is limited (Velde 2004).

Clay Dating by K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ Methods: A History and Literature Review

Clauer and Chaudhuri (1995) and Meunier and Velde (2004) summarized the impact, use, and limits of different isotope dating and tracing systems including conventional K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating of sedimentary systems. Armstrong (1991) and Clauer et al. (2012) summarized the scientific history and technical developments of the conventional K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ method applied to illite clay minerals. Fundamental nanoparticles of illite with sizes of $<0.02\text{ }\mu\text{m}$ or $<20\text{ nm}$ can be dated successfully (Clauer et al. 1997).

The concept of glauconite K–Ar dating was described by Odin et al. (1982). Smith et al. (1993, 1998) report $^{40}\text{Ar}/^{39}\text{Ar}$ dating of single grain glauconite minerals using micro-encapsulation to address ^{39}Ar recoil. Numerous glauconite dating studies are reported in the literature (e.g., Clauer et al. 2005; Derkowski et al., 2009). However, some controversy exists over the merits of K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ glauconite dating compared to zircons separated from the same stratigraphic units and dated by U–Pb geochronology (Selby 2009).

K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ Dating of Clays: Basic Principles

The K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ methods allow dating of clay minerals formed since the formation of the solar system (Dalrymple 1991) until a few thousand years before present (Renne et al. 1997), because of the relatively short half-life of about 1,250 Ma ago (Ma) of the ^{40}K isotope. Special care is required in dating young geological samples due to atmospheric $^{40}\text{Ar}/^{39}\text{Ar}$ contamination and error magnification (McDougall and Harrison 1999). Ages are reported to international timescales such as Gradstein et al. (2012).

The age of clay minerals determined by the K–Ar or $^{40}\text{Ar}/^{39}\text{Ar}$ method is valid when the following assumptions are satisfied:

1. The clay mineral must behave as a closed system. The system should not have lost any radiogenic ^{40}Ar produced by decay of ^{40}K , which requires a closed system relative to radiogenic ^{40}Ar and K since clay formation.
2. The radiogenic ^{40}Ar should only be produced by decay of ^{40}K . No ^{40}Ar should have been incorporated into the mineral after its formation.
3. The atmospheric ^{40}Ar should be adjusted to the present-day $^{40}\text{Ar}/^{39}\text{Ar}$ value of 295.5.

Dating authigenic clay mineral crystallization involves a fundamentally different approach from dating detrital clays (Meunier et al. 2004). Theoretical aspects that need to be considered when trying to date authigenic clay minerals include: (1) contamination effects, i.e., mixing with other K-bearing phases, (2) Ar closure, i.e., loss or capture of radiogenic ^{40}Ar during crystallization, (3) the duration of K accumulation, and (4) initial clay mineralogy (illite, illite–smectite).

There is a fundamental difference between the classical mineral cooling model, which is characterized by the Ar “closure temperature”, considered to be of short duration relative to the mineral “life time,” and that pertaining to clays (Faure and Mensing 2005). Dating clay minerals involves the assumption that a newly formed authigenic clay mineral can be dated by isotopic techniques independent of the concept of a closure temperature. This crystallization process can encompass different timescales. If the time interval over which an authigenic mineral has crystallized is shorter than the analytical precision of the method, described in 1 or 2 sigma values, an actual “age” is recorded. However, in some geological case studies, mineral authigenesis and crystallization can extend over extensive time periods, larger than the analytical uncertainties, and an “integrated age” is recorded (Meunier and Velde 2004). Smectite–illite-type minerals growing at any given temperature, labeled as the “Ar retention temperature” (~70 °C), will start the K–Ar radiometric chronometer. Instead of a simple cooling model, the K–Ar dating of clays may be subjected to further recrystallization episodes when the temperature exceeds the crystallization temperature (e.g., Clauer and Chaudhuri 1995, 1998; Meunier et al. 2004).

Ar diffusion effects have been investigated for fine-grained clay minerals. The general theory of Ar diffusion was summarized by Crank (1975) and Watson and Baxter (2007) and its geological applications to the K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ methods have been outlined by McDougall and Harrison (1999). Huon et al. (1993) described an Ar diffusion model using clay particle morphology as the shape of fine-grained clay minerals will influence diffusion. Models employing cylindrical, planar, and spherical shapes have been applied in investigating or constraining the influence of thermal overprints on the preserved ages in clay minerals. Moreover, only limited Ar diffusion parameters for illite (muscovite) have been published (Wijbrans and McDougall 1986; Harrison et al. 2009).

Clay Dating Methods

K-bearing clay minerals such as illite and glauconite can be dated by the conventional “spiked” K–Ar, the “unspiked” K–Ar, and $^{40}\text{Ar}/^{39}\text{Ar}$ methods.

Classical Spiked K–Ar Clay Dating

For dating K-bearing rocks or minerals, it is necessary to determine the concentrations of ^{40}K and of radiogenic ^{40}Ar on two aliquots of the same sample. Since two splits of any sample are required, a critical assumption of homogeneity of the sampled clays may be violated. Due to the hygroscopic nature of clays, special care has to be taken in the preparation of both K and Ar sample splits. For Ar analysis by noble gas mass spectrometry, sample splits are loaded into clean Al, Cu, or Mo foil, weighed and preheated to 80 °C for several hours to remove moisture, and reweighed using a high-precision balance. The measured dry weight is used in the K–Ar age calculation. For both K and Ar analytical procedures, international mineral standards and blank analyses are performed for quality control purposes. Farley et al. (2013a) developed a new double-spiked K–Ar dating method using a solid ^{39}Ar and ^{41}K spike for K and Ar isotope measurements. This method uses a single mass spectrometer and double spiking requires a single sample aliquot, enabling in situ age determination on other planet surfaces such as Mars (Farley et al. 2013b).

Unspiked K–Ar Clay Dating

The theory and analytical procedures of the unspiked K–Ar method have been summarized by Cassignol and Gillot (1982) and Sudo et al. (1996). The unspiked K–Ar method is able to date geologically very young basalt samples (several kyr) with high atmospheric ^{40}Ar contamination.

With the use of this procedure on clays, the initial $^{40}\text{Ar}/^{36}\text{Ar}$ is calculated from the present atmospheric $^{38}\text{Ar}/^{36}\text{Ar}$ isotope ratio assuming mass-dependent isotopic fractionation during mineral formation.

$^{40}\text{Ar}/^{39}\text{Ar}$ Clay Dating

The basic principles, applications, and analytical methods of dating clay minerals by $^{40}\text{Ar}/^{39}\text{Ar}$ dating are summarized by McDougall and Harrison (1999) and Clauer et al. (2012) and highlight technical challenges related to the micron-scale grain size of clay minerals. Numerous studies have documented the ^{39}Ar recoil phenomenon, resulting from irradiation of the samples by fast neutrons, needed to transmute ^{39}K into ^{39}Ar . This recoil effect, which can cause problems of isotopic loss at the surface of small clay crystals, represents a major disadvantage for clay $^{40}\text{Ar}/^{39}\text{Ar}$ dating, as a precise ^{39}Ar measurement is required to calculate indirectly the amount of K present in the mineral phases. Turner and Cadogan (1974) and Kelley (2002) calculated the distances of ^{39}Ar recoil during irradiation to be a mean of 0.08 μm , refined by Onstott et al. (1995) and Villa (1997). Foland et al. (1992) developed a sample encapsulation method, which allows capture of ^{39}Ar released during irradiation to correct $^{40}\text{Ar}/^{39}\text{Ar}$ ages of illite and glauconite (Onstott et al. 1995; Smith et al. 1993, 1998). Clauer et al. (2012) suggested that the encapsulation method requires a standardization process to allow comparison of data obtained in different laboratories. $^{40}\text{Ar}/^{39}\text{Ar}$ clay dating is controversial as shown by the literature, mainly due to different interpretations of the ^{39}Ar recoil effect (Dong et al. 1995; Yun et al. 2010; Clauer et al. 2011, 2012). In order to minimize ^{39}Ar recoil losses, special sample pre-treatments such as pre-heating under vacuum, compaction under vacuum, neutron irradiation in vacuum, and/or using a different neutron source (e.g., deuterium–deuterium) might offer new analytical pathways in reducing ^{39}Ar recoil effects (Kapusta et al. 1997; Renne et al. 2005).

Applications of Clay Dating

Clay minerals occur in different geological settings and are associated with soil formation, erosion and sedimentation processes, and diagenesis processes that occur during burial from surface locations (Velde 1992; Meunier and Velde 2004). The K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating of diagenetic events in sedimentary systems faces methodological challenges that are discussed within four main applications.

Deep Burial Clay Mineral Authigenesis in Sandstones

Dating of illite offers the prospect of establishing the absolute timing of diagenetic events such as heating or fluid flow events within a sedimentary basin (Pevear 1999).

The radiogenic isotope systematics of sedimentary rocks is complex due to the intimate mixture of minerals of different origins such as detrital phases possibly from a variety of sources and authigenic minerals. It is therefore often difficult to unambiguously interpret measured ages. Special sample preparation techniques involving freeze–thaw disaggregation to avoid over-crushing and extensive size separation to reduce the proportion of detrital phases have been developed (Liewig et al. 1987). Progressive size reduction to submicron size fractions ($<0.1\ \mu\text{m}$ or finer) increases the proportion of authigenic clay phases in the clay component and minimizes contamination. The most reliable isotopic ages for authigenic clay minerals are obtained from the finest size fractions. The validity and importance of the assumptions involved in K–Ar or $^{40}\text{Ar}/^{39}\text{Ar}$ dating of authigenic illite must be carefully addressed, and the sample material characterized using a wide range of methods such as

x-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), and particle granulometry. Authigenic illite formation is dependent on several parameters including: temperature and pressure ranges and formation fluid chemistry (Hamilton et al. 1992; Wilkinson and Haszeldine 2002). Variables that control the rate of illite growth are temperature, pressure, concentration of reactants (K, Si), rate of supply of reactants, pore fluid velocity, rate of diffusion or active fluid flow, time, and the presence of an aqueous pore fluid. Comprehensive summaries concerning authigenic illite dating can be found in Clauer and Chaudhuri (1995), Clauer et al. (2012), Hamilton et al. (1989, 1992), Worden and Morad (2003), Meunier and Velde (2004), and Meunier et al. (2004).

Smectite to Illite Transition During Burial Diagenesis in Shales

Since Aronson and Hower's (1976) pioneering study focusing on burial diagenesis in the US Gulf coast, numerous studies have investigated other basins (Clauer and Chaudhuri 1995; Girard et al. 1989). The implications for dating of the illite to smectite transition due to burial diagenesis have been summarized in Meunier and Velde (2004) and Frey and Robinson (1999). Illite ages are interpreted as maximum ages because the neoformed illite captured in the finest separated size fraction is formed at the ends of filamentous grains, representing the most recently grown illite, due to Ostwald ripening processes (see Eberl and Środoń 1988; Eberl et al. 1990). Illite grain-size fractions of neoformed illite are mixtures of illite particles formed at different times during growth, and this growth history is usually investigated by dating a range of different grain-size fractions (0.02 to 2–6 µm). Hunziker et al. (1986) and Pevear (1999) discussed the influence of detrital mineral phases on authigenic illite formation in detail for sedimentary systems. To resolve the influence of detrital contamination, a regression method was proposed (Pevear 1999), in which an extrapolated diagenetic age should represent the mean integrated age of the time interval over which illite crystallizes. This method addresses the contamination effect due to intimate authigenic–detrital clay mineral phase mixing at very small grain sizes (<2 µm). In a different approach focusing on the detrital clay mineral end-member, van Laningham and Mark (2011) reported $^{40}\text{Ar}/^{39}\text{Ar}$ standard mineral mixture step heating data and proposed a fine-grained bulk sediment provenance tool that can be applied to date clay minerals.

Glaucconite Dating for Stratigraphic Age Control

Glaucconite formation takes place during deposition of sediment at the water–sediment interface. Glaucconite is therefore an attractive target for isotopic dating of depositional ages of sedimentary rocks (e.g., Odin et al. 1982). Dating of K-bearing clay minerals using the isotopic systems offers the prospect of establishing the absolute timing of sedimentation. To ensure that the dated separates of authigenic glauconite provide meaningful stratigraphic ages, and to avoid any age bias by detrital contribution, Odin (1975) suggested that only glauconites with a K concentration above 5.4 wt% should be used for isotopic dating.

Deformation Events: Brittle Fault and Gouge Zone Dating

Displacement on discrete fault planes often results in the development of fault gouge composed of crushed rock fragments and authigenic illite clay minerals. Numerous studies have highlighted the potential for determining the absolute timing of brittle fault history using isotopic dating techniques including K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating (Vrolijk and van der Pluijm 1999; van der Pluijm et al. 2001; Zwingmann et al. 2004, 2010; Solum et al. 2005; Haines and van der Pluijm 2008; Viola et al. 2013). The understanding of fault processes and specifically the timing and extent of fault gouge formation are important for several reasons: (1) regional correlation of shallow fault activity that is of critical

importance in neotectonic studies, (2) for hydrocarbon exploration as faults may act as either a conduit zone or a seal for fluids and/or hydrocarbons, (3) CO₂ sequestration and possible CO₂ diffusion along fault zones, (4) civil engineering and the evaluation of earthquake hazards, and (5) in assessing the suitability of sites for waste storage such as nuclear waste.

Fault gouge illite grain-size fractions of authigenic origin are mixtures of illite particles formed at different times during growth, and this growth history is also investigated by dating a range of different grain-size fractions. ⁴⁰Ar/³⁹Ar dating of coarse-grained mica is a valuable tool in dating fault processes (Sherlock et al. 2003). However, as outlined, the dating of fine-grained micron size illite mineral fractions is complicated due to ³⁹Ar recoil and the consequent corrections. The inverse relationship between grain size and amount of contamination can therefore make dating of illite fault gouges problematic: the finest grain sizes are normally least contaminated but are influenced by ³⁹Ar recoil and therefore not suitable for ⁴⁰Ar/³⁹Ar dating without encapsulation. Fine-grained illite can easily be dated by traditional K–Ar and can distinguish authigenic and detrital illite clay mineral phases.

Summary and Conclusions

The conventional K–Ar and ⁴⁰Ar/³⁹Ar dating methods have both advantages and limitations:

1. K–Ar dating requires relatively large samples (ca. 50 mg) which can introduce inaccuracy with any sample heterogeneity as two sample aliquots are required for K and Ar analyses.
2. A major obstacle for ⁴⁰Ar/³⁹Ar dating is ³⁹Ar recoil resulting in potential loss of ³⁹Ar, which occurs during irradiation, mostly in the clay mineral size range below <2 μm.
3. ³⁹Ar recoil can be measured using an encapsulation technique that needs to be technically evaluated and standardized.
4. ⁴⁰Ar/³⁹Ar dating and the conventional K–Ar method are valuable tools for clay dating. Both methods have distinct applications in the field of clay geochronology.

Luminescence, Pottery and Bricks

Ian Bailiff*

Department of Archaeology, University of Durham, Durham, UK

Definition

The luminescence dating of ceramic materials, including pottery and bricks, is an experimental technique for determining the time elapsed in years since the ceramic material was produced by firing.

Introduction

The luminescence techniques for dating ceramic artifacts have been described in detail by Aitken (1985, 1998). Guidelines produced by English Heritage (Duller 2008) provide a concise overview of applying the method. Although the dating of sedimentary deposits currently forms the main focus of application, the dating of ceramics is discussed in a number of review papers (Liritzis et al. 2013; Preusser et al. 2008; Wintle 2008; Feathers 2003) and also by Wagner (1998).

Historical Perspective

When thermoluminescence (TL) dating was proposed as a new scientific dating method in the 1960s (Aitken 1985; Wintle 2008), the principle, based on the accumulation and storage of trapped charge in crystalline luminescent minerals, was demonstrated using pottery from archaeological contexts. Application to other types of ceramic artifacts, such as curated works of art (Fleming 1979) and ceramic building materials (CBMs), soon followed. The introduction of optically stimulated luminescence (OSL) techniques during the 1980s led to a focusing of research effort on the dating of processes associated with the deposition of (unheated) sediments. This type of application now dominates the field. Although testing of the earliest pottery of Late Pleistocene origin is within the chronological range of the method (Kuzmin et al. 2001), adoption of the method for dating pottery was muted, despite the common occurrence of pottery on many sites from the Neolithic onwards (Orton et al. 1993). For general application, the specialist advice needed for sampling made its deployment less convenient compared with radiocarbon testing, and moreover, the levels of uncertainty in luminescence dates were considered too high to improve on chronologies developed on the basis of pottery typology. Where suitable organic samples are unavailable or where temporal resolution is limited as a result of calibration issues (e.g., the flat spot ca 2500 BP or multiple ranges during the last 500 BP), the dating of many sites has relied on pottery typology, particularly fabric composition. It is in the testing of fabric chronologies where a particular role for luminescence dating of pottery has emerged. Also, after years of dormancy, a role has lately emerged for the dating of brick in standing buildings, and the application to medieval buildings and monuments lacking diagnostic features has become an active area of research.

Technical Issues

The luminescence age equation (Aitken 1985, 1998), expressed in its most compact form,

$$\text{Age} = \text{Paleodose} / \text{Dose rate},$$

is used to calculate the time elapsed since the chronometer mechanism was last reset (zeroing event), which occurs during the firing process in the case of a ceramic. The age, given in years before the year of testing, is accompanied by an overall uncertainty, given at the 68 % level of confidence (1σ), that is typically between ± 5 and ± 10 % of the age. The paleodose corresponds to the cumulative absorbed dose (in units of gray, Gy) received by grains of luminescent crystalline minerals within the ceramic sample (e.g., quartz or feldspar) since a zeroing or resetting event that is achieved by firing. Since resetting can be achieved for temperatures as low as ca 400 °C (i.e., baked or burnt clay), most well-fired archaeological pottery will have met this condition. Within the relatively short lifetime of a cooking pot, the effect of reheating on a fire has a negligible effect on the luminescence age, but if sherds were redeposited onto a ground surface long after burial and subjected to prolonged heating during a conflagration to temperatures in excess of those indicated above, the date of the destruction event would be obtained. The paleodose is determined experimentally (the basic techniques are discussed in Duller 2008) by applying luminescence techniques to many individual portions of grains of luminescent minerals extracted from the ceramic. The dose rate is usually determined by measuring the concentration of radionuclides present in the sample and the surrounding burial medium, and then applying conversion factors (Aitken 1985, 1998).

Paleodose

Most ceramic materials contain grains of luminescent minerals, such as quartz and feldspar, within the fine (e.g., <20 µm dia.) or coarse (e.g., 100–300 µm dia.) fractions of clays and temper, respectively. Such grains can be extracted in the laboratory by mechanical crushing and, sieving and the application of acid treatments. Typically a minimum of 25 g of ceramic is sufficient for dating measurements, although for some applications this can be reduced significantly by drilling (Fleming 1979). There are important differences in the luminescence properties of the two commonly present mineral types, quartz and feldspar, and this affects their use for dating measurements. In particular, trapped charge, which forms the basis of the chronometer mechanism, is retained without significant loss in quartz over archaeological timescales, whereas for most feldspars, there is a small but continuous loss due to a physical effect referred to as anomalous fading, which causes the age to be underestimated. Although a correction can be applied for the loss, this increases the uncertainty in the luminescence age, and each sample must be tested to establish the extent of fading since the rate of loss varies according to the geological source of the feldspar (Lamothe 2004). Hence, coarse quartz grains are usually preferred when testing ceramic materials, providing they are present in the fabric. Where this is not the case, extraction of the “fine-grain” fraction that usually contains both quartz and feldspar provides an alternative approach. Although feldspars can be selectively removed using acid treatment, the fine-grain technique for paleodose determination tends to be applied routinely without such additional treatment unless part of a methodological study.

Dose Rate

There are two physical volumes of interest when assessing the dose rate to grains in pottery: (a) the ceramic sample; (b) the surrounding medium to a distance of about 50 cm (Aitken 1985). Since the material within the latter contains radionuclides emitting gamma rays contributing ca 25–45 % of the

dose rate, where the proportion depends on the grain size selected for paleodose measurements, an assessment of the radionuclide content of both the ceramic artifact and burial medium is required.

Such assessment is more complex for samples adjacent to layers of soil with differing radionuclide composition or within surface deposits, for example, and for this reason the longstanding advice given (Aitken 1985) to select ceramic samples located within a uniform burial medium remains technically sound (Duller 2008).

For more complex situations, such as shallow or surface contexts, laboratories may use the fine-grain fraction for paleodose determination because a higher proportion (ca 75 %) of the dose rate is due to radioactive sources located within the pottery, and this reduces the dependence of the composition of the burial medium and the extent of overburden on the luminescence age. A further factor that has a bearing on sampling is the moisture content of both ceramic and the burial medium because it has a moderating effect on the dose rate. An average value for the moisture content during the burial period is estimated by the laboratory, and a conservative allowance is usually made for the uncertainty (typically ± 20 %) in the value adopted. Although the maximum moisture uptake of the ceramic, controlled by the porosity, can be measured in the laboratory, it is desirable to obtain samples of both pottery and soil stored with moisture content that is representative of the contemporary conditions within the burial environment. The overall precision in the luminescence age increases (lower uncertainty) in regions where there has been long-term aridity and decreases where the pottery is porous and the moisture content relatively high.

Luminescence Age

There is no internationally agreed specification for the presentation of luminescence dating results, but a listing of technical parameters related to the evaluation of the paleodose and the dose rate normally accompanies the luminescence age in publications and formal reports. The Ancient TL Date List, although no longer actively compiled, provided a systematic compilation of dating results and the last two issues produced included listings of luminescence dates for pottery from Britain (Barnett 1999) and the Southwest of North America (Feathers 2000); more recent guidance concerning aspects of date quotation is included in Duller (2008).

Pottery

Applications of the method to dating pottery can be broadly grouped into those: (a) establishing the date of the deposition of a layer or feature from which the pottery was recovered; (b) testing chronologies developed for pottery typologies; and (c) examining methodological issues, such as the feasibility of dating a previously untested type of pottery. There are several published large-scale dating studies, where the term “large scale” applied here refers to several tens of determinations rather than the several hundreds that could be envisaged with radiocarbon.

The accuracy of luminescence has been tested against independent dating evidence with pottery recovered from sealed contexts where its use before deposition was judged to be short lived. From a statistical analysis of the results for 24 sherds of diagnostic pottery of the British Iron Age (first millennium BC), an average difference of ~ 100 years was obtained between the luminescence dates and the mid-point of the assigned age range in each case (Barnett 2000). Similarly, comparisons of luminescence dates for pottery from short-lived Navajo sites of ca AD 1700 in North America with independent dating evidence provided by dendrochronology produced a favorable outcome (Feathers 2000, 2003).

On many sites, pottery is frequently undiagnostic and found scattered both spatially and temporally within the stratigraphy. Following fragmentation and discard, sherds may be redeposited in the filling of large features such as ditches, pits, and middens. Luminescence dating of pottery from sites in Britain and North America has confirmed that indiscriminate testing of redeposited pottery in large features will produce misleading results where the processes of manufacture and deposition are significantly displaced in time. However, luminescence has a constructive role to play by providing a means of testing chronologies for the onset and persistence of particular fabric types. The luminescence dates obtained in several studies on pottery from sites in Britain (Barnett 2000; Cramp 2006) and North America (Feathers 2009) challenge aspects of previously established fabric chronologies. In one region of Britain (Northampton), the incorporation of fine or coarse shell fragments in temper had been used to distinguish Early and Late Iron Age manufacture, corresponding to a separation of several hundred years, yet the luminescence dates showed that each type of temper was not confined to one of these periods and that the two groups strongly overlapped. In related work, the luminescence dates obtained for sherds of scored ware, although considered to be diagnostic pottery and thought to have been introduced during the 4th century BC, suggest much earlier introduction, in the 9th century BC and therefore a much longer chronological span of manufacture. Comparable issues have been raised by the testing of shell-tempered pottery from North American native sites in the Lower Mississippi Valley (Feathers 2009) and also sand-tempered fabrics from sites in southern Florida (Feathers 2003). While the majority of luminescence dates obtained for shell-tempered pottery from two mound sites were consistent with the assigned date range in the early eleventh century AD on the basis of the cultural assemblage and radiocarbon dates, luminescence dates of up to nearly a millennium earlier were obtained for several sherds from each site. These early dates, although considered enigmatic, flagged the possibility that relict pottery may have been brought to the sites by migrants. AMS radiocarbon dating applied to the carbonate temper to cross-check the reliability of the luminescence dates has since indicated that further work is required to evaluate the extent of a reservoir offset (Peacock and Feathers 2009) correction to the radiocarbon ages. Resolution of this issue represents an important test of both the capability of luminescence to provide a reliable tool for investigating the full temporal ranges of pottery chronologies and to further develop the combined application of independent chronometric techniques when dating pottery (Bonsall et al. 2002). While this aspect is being more actively investigated for North American pottery, work has also progressed sporadically on various sites across Eurasia and East Asia.

Due to the nature of the native North American mound sites, pottery is sampled from contexts that are very shallow or within erosional surfaces, and, as indicated earlier, the fine-grain technique can be applied to reduce the uncertainty in the dose rate, albeit with the attendant issue of anomalous fading to deal with if the feldspar minerals are not removed. The further development of such work has wider methodological implications for sites in other parts of the world where pottery surface scatters form a key component of the surviving archaeological evidence (Dunnell and Feathers 1994; Sampson et al. 1997) and where the testing of organic matter by radiocarbon is highly problematic because of postdepositional disturbance.

While evidence in the literature of research related to the dating of curated artifacts that builds on the early developmental work of the 1970s is sparse, its reactivation in a museum environment is leading to the incorporation of recent advances in experimental and statistical techniques (Zink and Porto 2005).

Ceramic Building Materials

The dating of ceramic building materials (CBM) is a natural extension of the dating of pottery in terms of the experimental techniques applied. Brick has been used extensively in the construction of buildings during the last two millennia. Although the literature is currently limited, examples of dating applications can be found for individual buildings and structures in Europe (e.g., the Czech Republic, Denmark, England, Finland, France, Germany, Italy, and Poland), in Asia (e.g., Cambodia, India, Sri Lanka, Thailand, and Uzbekistan), and in South America (Brazil). While precise dating of high-status buildings of the last millennium can be obtained to within a couple of decades or better, lower-status “vernacular” buildings of the Late Medieval and Early Modern periods in Europe are problematic; dating the construction and phasing of structural changes to better than 50–100 years are often difficult to achieve. In these circumstances, there is the opportunity for luminescence to make a contribution to the dating of brick buildings where an overall uncertainty in the date of ca ± 5 % of the age (± 25 years for a 500-year-old sample) can be approached. When applied to four buildings with reliable documentary and stylistic dating evidence in England, luminescence dating of brick produced extremely encouraging agreement (Bailiff 2007); for six samples taken from these dating control buildings (within the range ca AD 1400–1720), the mean difference between the central values of luminescence and assigned ages was 5 ± 10 years (s.d., $n = 6$).

The value of applying an absolute dating method is illustrated by studies that address wider research questions of chronology that are not bound by regional typologies and also extend beyond application to a single building. For the period following the Roman withdrawal from NW Europe during the early fifth century AD, in particular from Britain and Gaul, there has been a longstanding uncertainty regarding when the manufacture of CBMs was resumed. Recent work with bricks from a group of ecclesiastical buildings in NW France (Blain et al. 2007) and England (Bailiff et al. 2010) indicates that, while in France the practice of brickmaking was maintained during the Early Medieval period, it did not resume until the eleventh century AD in England. The testing of brick from Late Medieval buildings in England has also provided an initially unexpected outcome. Whereas it had been assumed that new bricks were produced for a specific building, the dates obtained for multiple bricks from a single building suggest that recycling was practiced by Late Medieval builders. This is of particular interest to building historians when assessing changes to, and loss of, buildings in urban and rural landscapes. However, the possibility of recycling CBM also provides a note of caution when sampling; in addition to a structural examination of the phasing of a building, the brickwork requires careful inspection for the use of recycled brick. In response to this issue, the possibility of dating the emplacement, rather than manufacture, of bricks has been explored by testing luminescent grains located within either the surface of a brick (Veilleigne 2007) or incorporated in lime mortar (Goedicke 2011) as long as the grains were sufficiently exposed to sunlight before use in construction and subsequently stored in dark conditions until tested in the laboratory.

Summary

After a prolonged period of gestation, two main methodological roles for the application of luminescence dating to archaeological ceramic materials have emerged; the building and testing of pottery fabric chronologies and dating the manufacture of ceramic building materials. When luminescence dates for pottery and brick have been tested against independent dating evidence in well-designed studies, the performance of the method has been found to be reliable and accurate within the estimated experimental uncertainties.

Obsidian Hydration Dating

Ioannis Liritzis*

Laboratory of Archaeometry, Department of Mediterranean Studies, University of the Aegean, Rhodes, Greece

Definition

Obsidian: Obsidian is an aluminosilicate, or rhyolitic, glass, formed by rapid cooling of volcanic magma under the proper geologic conditions. As any other glass, it is not a crystal, and thus it lacks the lattice structure typical of crystals at the atomic level. However, glasses do possess some degree of spatial order. Thus, it is an amorphous natural glass that contains pristine water H₂O and sparse crystals of variable sizes of a few microns. The surface is weathered in the atmosphere and the environmental context. Composition: 70–75 % SiO₂, 10–15 % Al₂O₃, 3–5 % Na₂O, 2–5 % K₂O, 1–5 % FeO₃ + FeO (in contrast to iron-bearing glass and silica-enriched leached rinds on obsidian glass recently discovered on Mars that are representative of global processes of explosive volcanism potentially implying widespread acidic leaching on Mars due to oxidizing and acidic solutions). Obsidian rocks were used by early peoples for the making of their tools and implements.

Obsidian Hydration

In its most basic aspect, hydration simply describes the process by which water is absorbed by obsidian and involves physicochemical changes in the glass (Doremus 2002; Anovitz et al. 2008; Liritzis and Stevenson 2012). The six steps of the process involve:

1. Environmental water molecules adsorb on the surface which exhibits roughness at the nanoscale creating a large surface concentration.
2. Absorption into the glass and diffusion into the interstices in the glass matrix occurs. The diffusion process seems to be driven by two properties of the water molecules: a concentration gradient and osmotic pressure or chemical potential. Although it has been suggested that chemical reactions play a role (Doremus 2002, 108 ff.), it is at present a matter of speculation.
3. A water saturation layer is then formed within a short period of time after the start of the diffusion process. Following this period, the saturated layer increases with depth as time progresses. The saturation conditions on the surface represent the average conditions of the physical surroundings for the diffusion system during the elapsed time in a particular archaeological context. It depends on factors that include the kinetics of the diffusion mechanism for the water molecules, the specific chemical structure of obsidian, as well as the external conditions affecting diffusion (temperature, relative humidity, pressure) (Liritzis and Diakostamatiou 2002; Liritzis 2006; Smith and Van Hess 1987).
4. The diffusing molecules stretch the glass matrix, causing an increase in volume in the hydrated region and a stress between unhydrated and hydrated regions.
5. Increased water concentration progresses into the glass, in time, its rate being a function of the initial openness of the glass, temperature, and the dynamics of the process itself.

*Email: liritzis@rhodes.aegean.gr

Fig. 1 (a) Schematic diagram of obsidian hydration of diffused water, (b) obsidian hydration rim seen through optical microscopy

6. When the hydrated layer becomes thick enough, typically greater than 20 μm , the accumulated stresses cause the layer to spall off as perlite.

Three general classes of methods have been proposed for measuring obsidian hydration: (a) measurement of water mass uptake or loss versus time by infrared (IR) (Ebert et al. 1991; Stevenson and Novak 2011; Stolper 1982), (b) direct measurement of water profiles versus depth by secondary ion mass spectrometry (SIMS) (Anovitz et al. 1999, 2004, 2008; Liritzis and Diakostamatiou 2002; Riciputi et al. 2002; Liritzis et al. 2004; Stevenson et al. 2004), and (c) observation of the leading edge of the stress zone by optical microscopy (e.g., Friedman and Smith 1960; Friedman and Long 1976; Stevenson et al. 1996).

The environmental water molecules entering obsidian glass depend mainly on (a) environmental temperature, (b) chemical composition, (c) mineralogical structure, and (d) intrinsic water content (see, Silver et al. 1990; Lanford et al. 1979). The deeper the water goes, the greater the time. The higher the environmental temperature in burial sites, the higher the diffusion rate, while for average environmental conditions it is $\sim 1 \text{ mm}/1,000 \text{ years}$ (Figs. 1a, b and 2a, b). Attention is exerted on the precise determination of “hydration front,” i.e., the interface layer between unhydrated and hydrated glass. It is a zone of optical contrast when seen under polarized light, due to the phenomenon of “stress birefringence” (Born and Emil 1980, pp. 703–705). Measurement of this layer can be determined to within $\pm 0.2 \mu\text{m}$ using digital imagery at higher magnification ($800\times$) (Ambrose and Novak 2012). A significant uncertainty can be introduced into the process as a result of poorly defined image quality stemming from improper sample preparation and weakly defined diffusion fronts. It has also been documented that diffused molecular water extends beyond the limits of the optical diffusion front (Stevenson et al. 2001; Tokoyama et al. 2008). Thus, the optical approach does not adequately document the full extent of the diffusion process.

Obsidian Hydration Dating (OHD)

The technique was initiated by Friedman and Smith (1960), where they noted that (a) the exposed surfaces of ancient obsidian artifacts had absorbed water, (b) the hydration birefringent rims were visible under high-power magnification (approximately $\times 500$), and (c) its width was dependent on time, chemical composition (i.e., obsidian quarry), and the temperature. They suggested that

Fig. 2 SIMS H⁺ profiles for three samples from Greece, Japan, and Slovakia

hydration process converts a hydration layer of measured thickness to an absolute date with an established rate for the inward diffusion of molecular water using the empirical Eq. (1):

$$X = (kt)^{1/2} \quad (1)$$

where X is the hydration rim width in microns (μm), k is the hydration rate at a particular temperature/relative humidity, and t is time.

The thickness (X) and the k , which is dependent on the specific archaeological site conditions, are required for age determination.

The hydration rim was initially measured by optical microscopy (Friedman and Smith 1960; Michels, et al. 1983; Stevenson et al. 1989a, b), but inaccuracies in the determination of the end point of the water front (Hull 2001; Stevenson et al. 2002; Anovitz et al. 1999) lead to measurements with other nonoptical techniques, like nuclear reaction analysis, infrared photoacoustic spectroscopy (IR-PAS), and secondary ion mass spectrometry (SIMS) (Stevenson et al. 2000, 2002; Lee et al. 1974; Tsong et al. 1978; Duerden et al. 1982; Liritzis and Diakostamatiou 2002; Anovitz et al. 1999).

The diffusion coefficient was estimated at high temperature (160 °C) and extrapolation to ambient site conditions using the Arrhenius Eq. (3) (Michels et al. 1983; Stevenson et al. 2002; Friedman and Long 1976).

Research subsequent to Friedman and Smith's original presentation has refined the method into two distinct techniques. The simplest referred to as *empirical rate dating* (Meighan et al. 1968; Findlow and Bennett 1978; Meighan 1976; Kimberlin 1976) requires correlating the width to optically measured rims to independent chronometric data, such as ¹⁴C (e.g., Ambrose 1976). The

second more complex and widely applied known as *intrinsic rate dating* requires experimentally determined rate constants and a measure of site temperature (Michels et al. 1983; Friedman and Long 1976; Stevenson and Scheetz 1989; Hull 2001).

The mathematical model utilized in the intrinsic rate OHD was

$$X^2 = A t e^{-E/RT} \quad (2)$$

where X is the depth, A is a source-specific constant, the diffusion coefficient ($\mu\text{m}^2/\text{day}$) is a pre-exponential constant, t is time, and E is the activation energy (calories or Joules per mole), respectively, R is the gas constant (calories per degree per mole, i.e., 1.987), and T is the absolute temperature (Kelvin), in fact the effective hydration temperature (EHT).

Along with this method, the importance of connate water, the compositional indices, and density, in controlling the hydration rate of obsidians, has been demonstrated by several authors (e.g., Ambrose and Stevenson 2004).

Nevertheless, the assumptions made by Eq. (2) are questioned from the sigmoid hydrogen profiles measured by SIMS (Fig. 2).

However, in spite of over 50 years of development and application, of the classical OHD versions has produced consistently reliable results, with the exception of some sites of young age and/or well calibrated to ^{14}C and typology. In some cases, ages have so contradicted other well-established chronometric data that the utility of the obsidian as an independent chronometer had been questioned. The problems with OHD are due to the use of inappropriate analytical techniques, which involved nonsystematic errors arising there from the inherent imprecision of optical measurements, the experimental conditions of estimation of hydration rate, the need for calibration issues, and an improper (empirical) model of the hydration process. The scientific background has illustrated the complexity of the hydration process, and revised working assumptions for OHD have been proposed (Anovitz et al 1999; Friedman and Long 1976; Ambrose 1976; Stevenson et al 2000; Riciputi et al. 2002; Braswell 1992; Hull 2001; Rindings 1996; Liritzis and Laskaris 2012; Liritzis et al. 2004).

An advancement of OHD with a completely new approach – the monitoring of hydrogen profile in obsidian surfaces by SIMS (see below) – suggests that refinement of the OHD technique is possible in a manner which improves both its accuracy and precision and potentially expands the utility by generating chronological as well as palaeoenvironmental and usage data (Liritzis and Laskaris 2011). An earlier attempt of using nuclear reaction to monitor H^+ by depth has not been followed up (Tsong et al. 1981).

Another recent example of progress with classical OHD is based on accurate measurement by IR-PAS and calculation of diffusion rates. The rate of environmental molecular water diffusion depends on the total structural water content of the obsidian found in the bulk glass. As the process of mass uptake is a function of temperature, pressure, and openness of the glass matrix as measured by intrinsic water concentration, mass gain or loss proceeds proportional to t^n , where t is time and n is an exponent lying between approximately 0.5 and 0.6 shown by IR-PAS analysis in a series of 90 °C isothermal laboratory hydration experiments (Stevenson and Novak 2011). Later on, Stevenson et al. (2013) have applied this developed calibration to estimate hydration rates for obsidian based upon the structural water content of the glass as determined by IR-PAS to 53 Rapa Nui, Easter Island, Chile. Here, the Arrhenius constants (i.e., pre-exponential, activation energy) may be estimated from $\text{H}_2\text{O}t$ (see below).

Accuracy of Hydration Rim Measurements

In a satisfactory laboratory technique, accuracy is not limited by resolution of the microscope to $\sim 0.25\ \mu\text{m}$, but probably lies in the range of $0.05\text{--}0.1\ \mu\text{m}$, which is consistent with data reported. In a practical sense, measurement accuracy is more likely limited by the material properties of the obsidian. In any case, the accuracy of rim measurement is not a large contributor to the error in computed age in OHD (Rogers 2010), who points that computing a hydration rate is *not* a regression problem, however, but a problem of parameter optimization.

However, the apparent rim accuracy thus achieved is not the main factor in age determination. Each data point is a combination of valid data and experimental error, with major errors arising from site formation processes, association with radiocarbon or luminescence dating or the archaeological typology and obsidian, uncertainties in temperature, and fluctuations in the hydration rate which are not accounted for.

OHD Based on SIMS and IR-PAS Methodological Approaches

Initiated by Tsong et al. (1980; 1981), OHD based on SIMS has been followed by dozens of articles on the application of SIMS on obsidian artifacts but most on the determination of hydration layer, the diffusion of cations, and the dating. The direct measurement of the water profile measurement is generally performed by SIMS or the IR-PAS. The principle is to measure the concentration of H^+ ions, as a proxy for water, as a function of depth. The depth of penetration is typically measured by the end point (tail) where the water concentration has fallen to the pristine water concentration value at the surface.

Two teams at Oak Ridge (USA) and Rhodes (Greece) relied on the modeling of the H_2O concentration profile as a function of hydration depth, but following them in different ways. As a result, the ODDSIMS and the SIMS-SS coined versions were produced, respectively (Anovitz et al. 1999, 2004; Liritzis and Diakostamatiou 2002; Liritzis et al 2004; Liritzis and Laskaris 2009, 2011).

In using SIMS, an ion beam (usually Cs) bombards the obsidian surface. (The dating is based on the concentration of H as a proxy for H_2O versus depth) (Fig. 3).

The use of SIMS on obsidian surface investigations, although relatively infrequent, has produced great progress in OHD dating. In essence, it is a technique with a large resolution on a plethora of chemical elements and molecular structures in an essentially nondestructive manner (Liritzis and Laskaris 2011).

Anovitz et al. (1999) presented a model which relied solely on compositionally dependent diffusion, following numerical solutions (finite difference (FD) or finite element) elaborating on the H^+ profile acquired by SIMS. A test of the model followed using results from Mount 65, Chalco in Mexico, by Riciputi et al. (2002). This technique used numerical calculation to model the formation of the entire diffusion profile as a function of time and fitted the derived curve to the hydrogen profile. The FD equations are based on a number of assumptions about the behavior of water as it diffused into the glass and characteristic points of the SIMS H^+ diffusion profile. In fact, the depth of the half-amplitude point of S-like H^+ profile is found to be proportional to t^n , where t is time and n is an exponent lying between approximately 0.6 and 0.7 (Anovitz et al. 1999, 2004; Stevenson and Novak 2011). The half-amplitude measurement is again a function of temperature and openness of the matrix; however, since the measurement is made to a half-amplitude point, i.e., a relative measurement, the technique is not sensitive to the total amount of water present and should not be affected by pressure.

Fig. 3 Overlapping of SIMS H^+ profile in atoms/cc versus depth, on the hydration layer (rim), into the obsidian glass (Liritzis and Laskaris 2011)

In Rhodes, Greece, one dating approach is based on modeling the hydrogen profile, following Fick's diffusion law, and an understanding of the surface saturation layer (surface saturation, SS) and surface topography (Liritzis 2006; Liritzis et al. 2004; Liritzis and Laskaris 2009). The saturation conditions on the surface represent the average conditions of the physical surroundings for the diffusion system during the elapsed time in a particular archaeological context.

It has been shown (Liritzis 2006) that all of the H^+ profiles are broadly similar in form; however, this is their only shared property. Despite the fact that they are derived from the same type of geological material, close inspection of the shape of the profiles suggests that definite differences are present. These which are derived from the significant environmental impact as well as intrinsic effects may alter the form of the SIMS hydrogen profile. It is these slight variations in the profile that are case specific, and this is the important observation that the calculated age by SIMS-SS method relies upon. Therefore, each age calculation is based on this diffusion profile, which is unique for every obsidian sample. There are three advantages to this fully intrinsic procedure: (1) the final shape of the hydrogen profile, properly modeled, incorporates two of the principal external and highly variable environmental parameters, those of temperature and humidity; (2) the use of SIMS instrumentation to measure surface hydration layers results in high precision thickness (depth) values with an error of 0.02–0.05 μm depending upon the degree of surface roughness; and (3) absolute age estimates may be calculated. The currently used two methods, one based on SIMS (namely, SIMS-SS, SS for surface saturation) and the other on IR-PAS, are briefly described below.

The SIMS-SS Method

The water diffusion coefficient at any particular moment is expressed by the first derivative of the hydrogen profile. Its inverse ratio is the apparent hydration rate. The average depth of surface saturation layer X_s and corresponding saturation concentration C_s obtained from the determination of the SS layer gives the overall error attached to the SIMS-SS ages.

Using the end product of diffusion, a phenomenological model has been developed, based on certain initial and boundary conditions and appropriate physicochemical mechanisms that express the H₂O concentration versus depth profile as a diffusion/time equation. The modeling of this diffusion process is a one-dimensional phenomenon, where the H₂O molecules invade a semi-infinite medium in a perpendicular direction to the surface. The model is based on the idea that in the SS layer located near the sample surface, that is, in the first half of the sigmoid curve, the C is assumed as constant along a very short distance. Thereafter, C gradually decreases following the trend of the sigmoid. In brief, the three principles used for dating are (a) the comparison of a nondimensional plot with a family of curves of known exponential diffusion coefficients; (b) the correlation between the rate of transfer (diffusion) from the surface with the diffusion duration, the saturation concentration C_s, the intrinsic (pristine) water concentration C_i, the diffusion coefficient D_s (defined the flux/gradient, where gradient or tangent = dC/dx), and the following Boltzmann's transformation and auxiliary variables; and (c) the modeled curve of diffusion profile (concentration versus depth) of Eq. (3) (see Liritzis et al. 2004; Liritzis and Laskaris 2012).

$$C = e^{a+bx+cx^2+dx^3} \quad (3)$$

The dating in Eq. (4) that has been proposed incorporates all the abovementioned parameters:

$$T = \frac{(C_i - C_s)^2 \left[\frac{1.128}{1 - \frac{0.177 k C_i}{C_s}} \right]^2}{4 D_{s, \text{eff}} \left(\frac{dC}{dx} \Big|_{x=0} \right)^2} \quad (4)$$

where C_i is the intrinsic concentration of water, C_s the saturation concentration, D_s = dC/dx the diffusion coefficient for depth equal to zero, D_{s,eff} the effective diffusion coefficient empirically derived from a set of well-known ages and Eq. (5) as the effective value of the diffusion coefficient D_s for C = C_s, and k is derived from the family of Crank's curve. It is:

$$D_{s, \text{eff}} = a * D_s + b / (10^{22} * D_s) \quad (5)$$

where D_s = (1/(dC/dx)) * 10⁻¹¹ assuming a constant flux and taken as unity (Liritzis and Laskaris 2009; Liritzis 2006; Brodkey and Liritzis 2004). Equation (5) and assumption of unity are a matter of further investigation.

Often, the obsidian surface at the micro- and nanoscale is not smooth, and this influences the diffusion of water and, as a result, the SIMS profile. Polarized light microscopy (PLM) and atomic force microscopy (AFM) (Fig. 4) have been used to examine the obsidian surface and investigate any correlation between the surface roughness and the SIMS measurements (Liritzis et al. 2007). As proposed by Liritzis et al. (2008a, b), a linear regression fit in the diffused region defines the dispersion which reflects the degree of surface roughness. The smoother the surface, the less pronounced the dispersion of the data points to either side of the trend line and the smoother the SIMS diffusion profile. The surface roughness measured by the AFM instrument is linearly correlated with the standard deviation of the residuals between the data points (H⁺ values of g/mol or atoms/cc) and the linear fit in the diffused region of SIMS. This proportionality aids the selection of appropriate obsidian samples/surfaces for dating and also for the proper choice of the spot where the SIMS analysis is performed. Last, the smooth variation of other monitored cation

Fig. 4 Atomic force microscopy on obsidian surface indicates surface roughness, most significant parameter for accurate SIMS H⁺ profiling (Liritzis and Laskaris 2009)

profiles (K, Fe, Si, Mg, F, Al) and mapping of ion rastered surface areas act as criteria for acceptable and safe further numerical evaluation of H⁺ profiles.

The validity of these new procedures is tested through a comparison with independently derived age determination. A suite of samples from Easter Island (Chile), Mexico, Greece, Japan, Asia Minor, and Hungary, ranging from few hundreds to 30,000 years ago, have been used, derived from archaeological contexts dated by the radiocarbon method or ceramic associations. Indeed, the convergence between the two dating methods is high (Figs. 5). The SIMS-SS age estimates fall within the expected age ranges for the archaeological contexts for all samples (Liritzis and Laskaris 2009; Liritzis 2010). Table 1 gives an example of two dates by SIMS-SS.

Obsidian Hydration Dating by IR-PAS

The application of IR-PAS (infrared photoacoustic spectroscopy) to the dating of obsidian was proposed as a solution for two central methodological problems associated with OHD using optical microscopy. *First*, optical measurements of hydration layer thickness from prepared thin sections rely upon a visual assessment of hydration layer strain birefringence to establish a depth of penetration. This strain is a secondary effect created by a volume expansion associated with molecular water diffusion that slows the passage of light through the hydrated layer. *Second*, it has been documented in numerous instances that the rate of water diffusion is significantly impacted by the amount of total structural water found within the glass matrix (Karsten and Delaney 1981; Zhang and Behrens 2000; Tomozawa 1985). Calibrations have been developed that correlate the concentration of structural water with laboratory hydration rates at lower temperatures (90 °C) (Stevenson et al. 1998; Stevenson and Novak 2011).

With the IR-PAS method, an absorbance spectrum associated with the vibrational modes of glass functional groups (Si-OH, Al-OH) and water peaks (OH, H₂O) is produced; at 3,570 cm⁻¹, it represents a combination band for OH/H₂O, and the band at 1,630 cm⁻¹ reflects the molecular

Fig. 5 SIMS-SS versus ^{14}C /archaeological ages for obsidians all over the world (Liritzis and Laskaris 2011)

Table 1 The SIMS-SS dates for two samples from Ikaria Island, Greece (Kerame site), without any other chronological control (From Liritzis and Laskaris 2012)

No.	Lab. No./site	Sampling details	X_s (cm)	C_s (grmol/cc)	C_i (grmol/cc)	e^k	$D_{s,eff}$ (cm^2/year)	Age SIMS-SS (years BP)
1	RHO-891 Kerame, Ikaria	T,C, Spit 4 Sq. 5 + 6	$3.1486\text{e-}5 \pm 1.87\text{e-}6$	$0.00129197 \pm 1.79\text{e-}5$	$0.000106014 \pm 6.24\text{e-}6$	360	$1.1365\text{e-}12$	$11,085 \pm 3,282$
2	RHO-892 Kerame, Ikaria	Trench D Spit 4	$4.90433\text{e-}5 \pm 2.24\text{e-}5$	$0.0007287 \pm 2.24\text{e-}5$	$9.8763\text{e-}5 \pm 4.44018\text{e-}6$	80	$3.42\text{e-}13$	$10,152 \pm 1,643$

concentration of H_2O whether structural molecular or diffused molecular water (Newman et al. 1986), as well as the structural water content of unhydrated region. The method is partially destructive since the artifact or flake must be cut to fit within the sample chamber and the IR-PAS peaks can be impacted by micro-cracks or voids within the glass that trap and retain molecular water. Stevenson et al. (2001) developed a calibration between IR-PAS intensity at $1,630\text{ cm}^{-1}$ and percent molecular water content ($\%\text{H}_2\text{Om}$), using polished and parallel-sided obsidian samples with a range in total water content from 0.09 % to 1.57 %. The rate constants are then calculated for an archaeological specimen. The 90°C diffusion coefficient (D) and activation energy value (E) are estimated from the obsidian total structural water content ($\%\text{H}_2\text{Ot}$) in weight percent concentration. The quantity k in age equation is estimated from the Arrhenius equation:

$$k = D \exp(-E/RT) \quad (6)$$

where D is the diffusion coefficient for H_2Om at 90°C , E is the activation energy in J/mol , R is the gas constant (8.314 J/mol K), and T is the hydration temperature (Kelvin). The archaeological site

temperature is determined for this application by direct measurement of soil temperature using cells monitoring T for 1 year. The resulting rate was then used to estimate ages for obsidian artifacts.

Recently, 52 obsidian specimens were measured at two sites of Rapa Nui Easter Island, Chile. Average measurements per parameter and deduced age for the sample 23 of site 15–233, test unit 2 were as follows: temperature as a function of specimen depth (not really an effective hydration temperature), 22.1–23.4 °C; PAS hydrated 1,630 cm⁻¹, 0.1025; %H₂Ome (environmental diffused molecular water) in hydration layer, 0.10 %; 3,570 cm⁻¹ PAS polished, 0.1313; structural %H₂Ot, 0.89; D at 90 °C as %H₂Ome^{0.5}/day, 0.000000118 (exponent 0.5 as in Eq.(1); E (J/mol), 84.450; diffusion rate estimated (%H₂Ome^{0.5}/year), 0.000027000; and dates, A.D. 1,419 ± 30 to A.D. 1,842 ± 30 years. Ages resulted in an acceptable degree of agreement with radiocarbon ages that those parameters can be used for other obsidian specimens excavated at the island (Stevenson et al. 2013).

However, at Rapa Nui, three problems come into play, which may be applicable to all methods. (i) Handling difficulties and the lack of artifact clarity call for different sampling methods to obtain structural H₂Ot and diffused H₂Ome concentration values.

The amount of damage to an artifact may be substantial when the thick section is removed, and in the worst of cases, small obsidian flakes may be completely destroyed or too small to be processed at all. In addition, opaque obsidians, which constitute a large proportion of the world's natural glasses, may not achieve clarity even after thinning glass thick sections to 0.5 mm. These same issues apply to processing a second subsample in order to measure the hydrated surface. (ii) Laboratory applications of obsidian hydration dating include multiple sources of error that impact the precision of a final age determination. The precision errors cannot simply be added to estimate a total error because the variables are independent of each other with the first associated with a concentration value and the second to a rate coefficient. The latter however seems to coincidentally provide a correct value from hydration experiments at 90 °C, while the used annual results of ambient T need further clarification. (iii) The EHT is a problem that in the above example at Easter Island seems to be overcome due to the short time archaeological intervals involved, since present T measurements are similar for the last say 2–5 hundred of years, but cannot be as such for a few thousand of years BP.

Diffusion Mechanisms in Obsidian

Considerable complexity of phase states has been indicated by a wide range of variability of properties from obsidian sources. The exact mechanism by which water diffusion in such amorphous glasses takes place, by either mechanical transport or molecular interconversion, is still subject to research (Doremus 1969, 2000, 2002; Nowak and Behrens 1997; Zhang et al. 1991; Zhang and Behrens 2000; Crank 1975). In either case, diffusion reaction is described approximately by Eq (7):

$$\partial W / \partial t = \partial (De \partial W / \partial x) / \partial x, \quad (7)$$

where W is concentration of total water, H₂O + OH⁻ (Doremus 2002, pp. 109–110; Zhang and Behrens 2000), and De is the effective diffusion coefficient given by Eq. (8):

$$De = 2WD / \beta, \quad (8)$$

where D is a constant diffusion coefficient characteristic of molecular H_2O and β is a proportionality constant related to the Ostwald solubility of water in obsidian (Doremus 2002, pp. 78, 110). The general solution of Eq. (7) requires numerical techniques and has been a subject of various considerations (Crank 1975), while an elaboration based on Fick's law has led to new age approaches by SIMS (Liritzis et al. 2004; Liritzis and Laskaris 2011; Anovitz et al. 1999).

Accelerated hydration experiments have shown that the diffusion of water is a complex and dynamic process (Anovitz et al. 2004; Stevenson and Novak 2011). The very early stages of hydration exhibit a high surface water concentration, a declining diffusion coefficient, and an advancing diffusion front. This change may be due to glass surface relaxation as the stress that built up in the near surface region is released. However, there may be a difference in the mechanism behind the early stage of water diffusion that differs from the longer-term developmental process.

Following the work of Doremus (2000, 2002) and Liritzis (2006), Stevenson and Novak (2011) hypothesized that H_2O_t creates a more open glass structure which allows water molecules to pass through "gateways" in the silica tetrahedra. It was their observation that the greater the concentration of H_2O_t , the faster the diffusion rate of ambient water (H_2O_m) into the obsidian surface.

Water enters obsidian glass at environmental temperatures as molecular H_2O and as hydroxyl OH formed by reaction with the glass silicate structure. It is believed that the occurrence of greater amounts of Si-OH in the network (silanols, referred to the intrinsic water molecules which may be present as OH- with the siliceous network) may weaken the neighboring Si-O-Si bonds, causing them to easily break, and therefore lower the overall activation energy (Brückner 1970; Ericson et al. 2004). However, the latter view may be revised as silanols seem to follow hydrogen sigmoid profile due to diffused water (see, Fig. 9, Liritzis and Laskaris 2011).

At any rate, as water enters the glass network, the structure is depolymerized and hydrogenated and silanol ions are formed (Si-OH) and allow additional water to enter the glass at a faster rate, while in the course of time, chemical reaction follows Fick's law. This changing diffusion coefficient results in the formation of the characteristic S-shaped concentration-depth profile (Fig. 2).

According to another model, H_2O molecules choose various diffusion paths in a nonhomogeneous way, as the size-dependent mechanism assumes that water molecules of radius $R_w = 0.15$ nm occupy interstitial sites of the obsidian and pass through "doorways" of radius R_D jumping from one doorway to another. The $R_D = 0.1$ nm derives from the equation regarding activation energy E , which is recognized as the elastic energy necessary to dilate a spherical cavity from radius R_D to R (Doremus 2002; Liritzis 2006). The rate at which this process occurs depends upon the intermolecular distance of the host material matrix compared to the size of the diffusing species.

This diffusion process forms an external layer as water leaves the atmosphere and humid sediment and diffuses into the glass structure. In particular, the surface saturated layer (SS layer) is formed in the first 1–3 μm of the obsidian surface through two diffusion mechanisms. The first mechanism transfers the ambient water from the environment into the exterior surface of obsidian, and the second mechanism is responsible for the diffusion process into the interior of the artifact (Liritzis and Diakostamatiou 2002). The mechanism of water diffusion in obsidian and the exponent of time in Eq. (1) are still a matter of investigation.

Discussion of Some Issues Related to Conventional OHD

A variety of strategies have been developed over the years to calibrate the movement of ambient water into a glass, to take into account the composition of the glass, and to model the environmental

history of the artifact context (e.g., temperature, humidity). In essence, the rate of hydration is dependent on the obsidian chemistry, the intrinsic water content of the glass, the temperature and relative humidity, and the chemistry of the diffusing water (Friedman and Long 1976; Ambrose 1984; Mazer et al. 1991; Friedman et al. 1994; Stevenson et al. 1998; Stevenson et al. 2002; Ambrose and Stevenson 2004; Rogers 2008, 2012).

Presently, the exponent of Eq. (1) is being questioned as non-applicable to all environments, and the determination of the diffusion coefficient from extrapolation of laboratory hydrated obsidians down to ambient conditions from the Arrhenius plot is considered as insecure (Anovitz et al. 1999; Stevenson and Novak 2011; Liritzis and Laskaris 2011). Several decades of research illustrated the complexity of the hydration process, and *revised* working assumptions or disillusiones for OHD were proposed (Mazer et al. 1991; Stevenson et al. 1998, 2000; Rogers 2007; Ridings 1996). In spite of many years of development and application, mainly from research groups in the USA and Australia, it appears that neither approach has produced consistently reliable results. In some cases, ages have so contradicted other well-established chronometric and/or typological data that the utility of the obsidian as a chronometer has been questioned (Anovitz et al. 1999; Ridings 1996; Liritzis 2006; Rogers 2008; Eerkens et al. 2008).

Although OHD seemed to give good relative ages in some case studies as in Easter Islands (Stevenson et al. 2000; Stevenson et al. 2013), practitioners of the measurement pointed to significant errors in other cases (Ridings 1996). The problem of determining accurately the hydration thickness is solved with new techniques such as infrared spectroscopy (IR), SIMS. Infrared spectroscopy has been used to measure the bulk water content of obsidian (Newman et al. 1986; Zhang et al. 1996) with the photoacoustic method (IR-PAS) used to quantify the depth of surface water diffusion (Stevenson et al. 2001, 2002; Stevenson and Novak 2011). The latter approach to hydration layer depth assessment has been calibrated relatively to SIMS and shown to have a higher precision and accuracy than obtainable by optical microscopy (Ambrose and Novak 2012).

In certain cases, extensive lab experiments using the same obsidian source, diffusion rate, and average environmental hydration temperature (effective hydration temperature) using temperature cells yielded satisfactory ages. These were controlled by available ^{14}C ages and ceramic typology, e.g., for south coast of Peru, using petrographic microscopic rim measurements (Eerkens et al. 2008), and Hopewell culture (Stevenson et al. 1998, 2004), using rim measurements by SIMS.

To summarize, the early problems with OHD were partly due to inappropriate analytical techniques involving (i) nonsystematic errors arising from the inherent imprecision for optical measurements, (ii) the experimental conditions and data of estimation of hydration rate, and (iii) on a theoretical plan an improper model of the hydration process.

Laboratory-induced hydration does not produce commensurable results with the in situ-induced hydration and/or silica dilution (Morganstein et al. 1999; Bartholomew et al. 1980). This was the case even when using a long-term artificial aging experiment with the obsidian samples from three separate volcanic provinces in Papua New Guinea exposed in normal air and water vapor pressure to controlled temperatures of 10 °C, 20 °C, 30 °C, and 40 °C, for up to 26 years (Ambrose and Novak 2012). Nevertheless, the latter confirm the value of the strategy by providing basic hydration rate constants for obsidian specimens from each of the three major Papua New Guinea sources. But in an archaeological context, these data still require calibration for an optical microscopy hydration measurement. SIMS provides an enhanced measurement system and is combined here with experimentally determined rate constants to independently cross-check radiocarbon dates and site temperature calculation at a ~2,100 BP archaeological site from Papua New Guinea. In fact, Ambrose and Novak (2012) noted that the error figure in age indicates the wide divergence from hydration reading error alone, while additional temperature-based error is even greater than the reading error

by a few hundreds of years and underlines the critical influence of temperature in attempting to derive absolute age values from obsidian hydration dating.

At any rate, the involved age in Eq. (1) is still empirical, surely far apart of the more satisfactory phenomenological approach and certainly not well substantiated by a scientific approach (Brodkey and Liritzis 2004).

Sources of uncertainty in OHD include hydrous and compositional chemistry, humidity, rim measurement, temperature history, diffusion rate variability due to intrinsic water and determination by extrapolation from higher temperature experiments, site formation processes, and age errors from comparative methods (with ^{14}C , archaeological typology) which affect the validity of the age-rim association.

Nevertheless, in spite of rigorous statistical modeling and error propagation, the evaluations of all sources of error impart uncertainties in each variant factor such that the span of uncertainties may sway between extreme percentages of the order of some 10s of a percent. The issue of considering any individual specimen and burial location as a unique case is a rule. Along this direction, calibration models per excavated site are always useful but are cumbersome and timing. A brief evaluation of main factors related and affecting the traditional OHD is described below.

Temperature

Perhaps the biggest problem is temperature, since the hydration process is strongly temperature dependent and the temperature history of an artifact can never be completely known. Past historical temperatures vary over time, both annually and diurnally, and hydration rate of obsidian is temperature dependent. The effect of the varying temperature is coined by the concept of *effective hydration temperature* (EHT), defined as the constant temperature which yields same hydration results as the actual time-varying temperature over the same period of time and can be computed from the time average of D (Rogers 2007). Because of the mathematical form of the dependence of hydration rate on temperature, $\text{EHT} \geq T$ mean. In fact, few degrees in error of EHT in the Arrhenius equation (embedded in Eq. (2)) produce errors of several centuries. For an activation energy (E) of 85 KJ/mol, the error in age for $\pm 1^\circ\text{C}$ is ± 11 – 13% , for $\pm 2^\circ\text{C}$ is $\pm 25\%$, and for $\pm 3^\circ\text{C}$ is around $\pm 37\%$. The well-known modifiers of obsidian hydration rate with temperature (the others being chemical composition and water vapor pressure) may be accounted for, but none is sufficient for precise prediction of hydration rates. For this reason, obsidians still need to be independently assessed for their own specific rate determination. On the other hand, another reported temperature approach using a set of calculated temperature parameters for one site based on a regional temperature scaling analysis contains uncertainties too and can further be corrected for first-order changes in paleotemperature if proxy data are available (Rogers 2010, 2012; Rogers and Yohe 2011; West et al. 2007). Even so, it is unlikely that EHT can be corrected much better than $\pm 1.0^\circ\text{C}$ (Rogers 2007). EHT includes the effects of temperature history in one parameter; furthermore, a change in EHT (Δt_e ; t_e is effective hydration temperature) produces a change in rim value (Δr):

$$\Delta r/r = -\frac{1}{2} (E/RT_e^2) \Delta t_e \quad (9)$$

For $E = 20$ KJ/mol and 90 KJ/mol, Eq. (9) gives 0.0140 and 0.0630, respectively, with a median E value of 0.0007 per KJ/mol. The former leads to a change in rim of about 1–6 %/ $^\circ\text{C}$, and the higher holds for nominal conditions. A cautionary note is that the meteorological data are for air temperatures, while obsidian usually is found at a variable depth in the ground where T differs. Alternatively, sensors (e.g., HOBO H8 Family loggers, e.g., Stevenson et al. 2013) are put over a year in situ that record a meaningful annual context meteorological average.

Rim

Typically, the mean and standard deviation of an aggregate of about six individual readings is taken for each hydration rim measurement reported by a laboratory. Standard deviations are nearly always $<0.1\text{ }\mu\text{m}$, more often $0.05\text{--}0.01\text{ }\mu\text{m}$. A previous analysis (Scheetz and Stevenson 1988) concluded that the accuracy is constrained by the resolution of the microscope system to $\sim 0.25\text{ }\mu\text{m}$ or worse; however, the issue here is not resolution but accuracy of coincidence measurement, which is well known to be about two orders of magnitude better than resolution (Jacobs 1943, pp. 86–88), so the error values quoted by obsidian laboratories are reasonable but the precision weak as recent methods have shown. A comparison of optical readings with hydrogen profiles collected by SIMS (Anovitz et al. 1999; Stevenson et al. 2001) and infrared profiling (Yokoyama et al. 2008) show that the depth of water diffusion extends well beyond the optically defined diffusion front. As a result, optical techniques cannot accurately track the diffused species. SIMS has been used to significantly increase precision to $\pm 0.05\text{--}0.1\text{ }\mu\text{m}$, but the cost per sample is prohibitive for routine application.

Higher precision of the rim reading is achieved by SIMS profiles or IR-PAS peak integration (Anovitz et al. 1999; Stevenson et al. 2001, 2002).

Diffusion Rate, D

Simulation experiments of hydration rate by laboratory methods (sometimes known as “induced hydration”) have an equivocal history in archaeology, and since it depends on temperature, attempts have been made in the past to measure hydration rate in the laboratory (e.g., Friedman and Long 1976; Stevenson et al. 1998). However, rates measured in the laboratory often have not agreed well with archaeological data (see, e.g., the pointed observations in Hall and Jackson 1989, p. 32), while in other cases agree (e.g., for Rapa Nui Easter Island, Stevenson et al. (2013) and in Topaz Mountain obsidian from Utah, Rogers and Duke (2011)). The hydration rate of obsidian, which is strongly temperature dependent, is allowed to proceed at elevated laboratory temperatures, when measurable hydration rims develop in days rather than years. The temperature dependence of the hydration rate has a well-attested mathematical form, so the principle of laboratory hydration is to hydrate a set of obsidian samples at elevated temperatures, determine the activation energy and diffusion constant, and then compute the hydration rate for temperatures of archaeological interest. Initially, the diffusion rate D was calculated from hydration that was experimentally induced under controlled laboratory experiments for use in the Arrhenius plot, in a high temperature range ($90\text{--}250\text{ }^{\circ}\text{C}$) (Stevenson et al. 1998). First, this did not secure safe extrapolation to much lower temperatures, and second, the simulated hydration does not produce the anticipated behavior with obsidian of similar source. Making use of nano-SIMS and simulation experiments, rates are produced at environmental conditions. Such an aging experiment for Papua New Guinea obsidians has shown differing diffusion rates for the same temperature and different storage temperatures of four different sources. There, the SIMS profile depths and regression results for the four hydrated obsidians, namely, Igwageta, Mt Bao, Wekwok, and Umleang, produced diffusion rates that vary by $\sim \times 25$ for a fourfold temperature increase, between $10\text{ }^{\circ}\text{C}$ ($0.002\text{--}0.004$) and $40\text{ }^{\circ}\text{C}$ ($0.06\text{--}0.10$) for the four different sources, which, however, have no marked chemical composition variation (Ambrose and Novak 2012). From room temperature to $75\text{ }^{\circ}\text{C}$, the diffusion coefficient changes by two to three orders of magnitude confirming the well-known sensitivity of the intrinsic dating technique to assumed local temperature (Anovitz et al. 2004).

This had resulted in high measurement error stemming from the use of optical methods; thus, the regression constants also had a large inherent error. But, data have shown a relationship between structural water concentration and D , and an increase in precision is now achieved through the

analysis using infrared measurement of experimentally developed hydration layers (Stevenson et al. 2001).

The errors and their affects have been exhaustively analyzed (Rogers 2010). Hydration rates can be reliably estimated by least squares techniques applied to obsidian-radiocarbon data with errors of about 4–5 %, while rates estimated by least squares techniques applied to time-sensitive artifacts are somewhat worse, with about 8–10 % errors. Rates determined from laboratory techniques (induced hydration) are somewhat more accurate, with about 2–3 % error.

Analytical errors concern (a) the mathematical procedure of a least squares best fit to the logarithmic Arrhenius equation (see Stevenson and Scheetz 1989; Rogers and Duke 2011), especially if data-point weighting is not included (otherwise the activation energy and diffusion constant will be in error); (b) the procedural error that involves laboratory techniques (e.g., erosion rates and rim growth, use of proper hydration environment and temperature); (c) the “scaling” problem, i.e., hydration at high lab temperatures and archaeological temperatures (the scaling is actually a complex function of the both hydration rates (and diffusion constant) and their activation energies and requires knowledge of both for each obsidian source in question); and last, but not least, (d) the role of phenocrysts presence (size and abundance) and obsidian transparency should also be reexamined for they obviate ideal diffusion process.

The Dependence of Time

The dependence of time on the square exponent of x has been questioned (Anovitz et al. 1999, 2004; Liritzis 2006). That is why most reported OHD ages are compared with other dating means (^{14}C , luminescence, ceramic typology), an expected practice for the initial development of the method, though in several cases the square root is valid.

The Surface Loss

The surface loss is identified as an important factor in glass hydration dating (Ambrose 1976, 1994; Liritzis et al. 2008a, b; Morganstein et al. 1999). Once present on an artifact with fissures, the surface dissolution rate of an obsidian artifact can be calculated. Although OHD theoretically is capable of yielding accurate dates in the range 1,000,000 to 200 years B.P. (Michels 1986), the obsidian surface is subjected to environmental flaking, and this limits its range; on the other hand, the nano-SIMS technology at least provides an accurate minimal rim reading that can deal with this issue.

Humidity

Humidity effects are relatively small and are typically ignored in analysis. However, the effect of accelerated hydrations with 100 % Rh on diffusion kinetics has not been adequately studied.

Intrinsic (Pristine or Connate) Water

The remaining variable hydration associated with original fast cooling of lava is an extremely important factor in the diffusion rate. The hydration rate in obsidian at any given temperature is a function of the concentration of water in the glass (Karsten and Delaney 1981; Karsten et al. 1982; Stevenson et al. 1998; Zhang and Behrens 2000; Zhang et al. 1991). Intra-source variability in intrinsic water content has been observed in Coso obsidians from eastern California, USA (Stevenson et al. 1993), and is likely present in others; thus, measurement of intrinsic water content per individual specimen is required as a prerequisite (Stevenson et al. 2001, 2002).

Some Early and Recent OHD Applications and Development

Friedman et al. (1997) provided a substantive review and summarized the problems linked to OHD and referred to case studies including archaeological specimens from New Mexico, central Mexico, Belize, Honduras, and Ohio (the latter imported from Wyoming). Studies of Mexican, Guatemalan, and Sardinian obsidians by Michels and his colleagues however are critiqued therein. The authors cross-dated OHD results with radiocarbon dating, archaeomagnetism, and ceramic phasing. Particular points to take care of included the factors related to hydration rates (as chemical composition of obsidians, their trace elements content, relative humidity, and regional rates), laboratory techniques (preparation of thin sections, optical measurement of hydration rim/rind thickness), and the conversion of hydration rate data to age. In their review, OHD was however promoted as a relatively inexpensive and “simple” scientific technique for determining absolute chronologies, so that the current masterful treatments presented replaced the earlier general assessment.

A series of OHD dates was reported consecutively by the UCLA laboratory (see Meighan and Scalise 1988).

Braswell (1992) pointed out problems concerning laboratory determinations of diffusion rate constants and the estimation of EHT in the field, from a study of the Coner Phase at Copas (Honduras). He concluded that the laboratory-induced rate constants used to determine these dates were of questionable validity and needed to be independently assessed. He showed how an error of but a few Kelvin in estimated EHT can lead to dates that are in error by several centuries. In view of the likelihood of large errors in the Copán obsidian dates, the assertion that the Late Classic Coner phase should be extended beyond 900 A.D. was considered therefore premature (Braswell 1992; Webster and Freter 1990)

Further application in OHD includes the dating of New Zealand obsidians by Stevenson et al. (1996), with a recent age span from 13th to 18th A.D., where hydration rates were calculated on the basis of obsidian water content as estimated from artifact density, while effective hydration temperatures were established from published temperatures derived from thermal cells. The deduced hydration dates have been successfully compared with radiocarbon dates from six archaeological sites in the North Island of New Zealand.

Ambrose (1994) gave a provisional age-depth model for hydration thicknesses for the Pamwak site, Manus Island, Papua New Guinea, spanning from 4 to 13 ka BP, based on internal crack surfaces and compared satisfactorily with ^{14}C age control.

Obsidian hydration dating has served as one of the chronological indicators for the Hopewell Culture earthworks (ca. 200 B.C.–A.D. 500) in central Ohio (Stevenson et al. 2004). This work presented new obsidian hydration dates developed from high precision hydration layer depth profiling using SIMS, and the data suggested that long-distance exchange in obsidian occurred throughout the Hopewell period. From Eq. (2) parameters, diffusion coefficient A and activation energy E were estimated by the density versus OH^- plot; EHT from cell pairs put in the site and Eq. (2) resulted in OHD age estimates that range between 258 and 119 B.C. and A.D. 607–94, and these incorporate the entire Hopewell period, as determined by absolute C-14 dates of the same site.

Based upon the water diffusion in natural glass, Stevenson et al. (2007) introduced the conventional OHD technique to dating high-calcium manufactured glasses with first preliminary results on seventeenth-century North American glass wine bottles manufactured by European settlers, concordant with historical data.

In many cases, intact internal fissures as concealed cracks can be used for OHD, and the rate of surface loss can be calculated from paired readings of these inner surfaces and the outer weathered

(depleted) ones (Ambrose 1998). When secondary rate factors for these fissures were compared to radiocarbon-based rates, a discrepancy was found due to dissolution.

At any rate, since OHD is dependent on processes which have occurred since an artifact was created, it can never be as accurate and reliable as radiocarbon or dendrochronology, and it should be always a secondary source of chronological data. Thus, in this frame, using a radiocarbon assay remains the basis for relative hydration dating; but this raises again the question, for a given site, of the true association of the artifact and the ^{14}C date and, for nearby sites, the remaining uncertainty of the validity of the constancy of environmental characteristics.

The ongoing Easter Island OHD by Stevenson et al. (2011) with more than 800 obsidian specimens analyzed has been advanced with the IR-PAS measurements of D and water, and ages are comparable to ^{14}C ones in the time span of fourteenth to nineteenth century A.D.

SIMS-SS has been applied to obsidians from several parts of the world (e.g., Greece, Chile, Turkey, Japan, Hungary, the USA) with ages from a few hundred to 30,000 years BP (Liritzis and Laskaris 2009, 2012).

Analysis of errors shows that it is unrealistic to expect age errors much less than 15–20 % in obsidian hydration dating (Rogers 2010). With those uncertainties in the computed ages, great caution must be exerted in inferring occupation duration of a site used based on OHD.

Conclusion

The process of hydration in glasses is very complex, involving chemistry, physics, and mathematical modeling. Obsidian hydration has certain weaknesses in terms of a chronometric tool like any other dating method. At any rate, two fundamental equations involved need further experimentation or prior calibration: an age equation of classical OHD and a temperature dependence equation, which is usually of the Arrhenius form and the SIMS-SS. Since the transport parameters being measured differ, the age equations differ slightly as well, in particular the exponent of the time (age) variable. It is likely that the parameters of the Arrhenius equation are slightly different as well, although investigations of this point have not yet been reported. However, it would be unwise to apply, say, an activation energy determined from water mass uptake to the optical (classical OHD) case without careful study or EHT and hydration experiments at ambient conditions.

Despite the fact that the classical OHD is furthest removed from the basic physics of hydration (criticism by advocates of other techniques, e.g., Anovitz et al. 1999; Liritzis and Laskaris 2012), it is still being used since it seems to satisfy coarse chronologies especially of recent centuries, whereas other chronometric data are frequently lacking (Stevenson et al. 2013). The alternative SIMS-SS with the mathematical techniques discussed also offers satisfactory dates for the past 30,000 years (Liritzis and Laskaris 2009, 2011, 2012).

Probably, the greatest needs at present are for (1) a more scientific approach of the age equation; (2) more dates on a “join forces” basis, for the two current approaches, for specimens throughout the world, and comparison with luminescence and C-14; and (3) development of not expensive versions of OHD.

Ar–Ar and K–Ar Dating

James K. W. Lee*

Department of Geological Sciences and Geological Engineering, Queen's University, Kingston, ON, Canada
Department of Earth and Planetary Sciences, Macquarie University, Sydney, Australia

Synonyms

(Argon–argon): Ar–Ar, ^{40}Ar – ^{39}Ar , $^{40}\text{Ar}/^{39}\text{Ar}$, ^{39}Ar – ^{40}Ar , $^{39}\text{Ar}/^{40}\text{Ar}$, argon-40/argon-39;
(Potassium–argon): K–Ar, ^{40}K – ^{40}Ar , ^{40}Ar – ^{40}K

Definition

Potassium–argon dating. An absolute dating method based on the natural radioactive decay of ^{40}K to ^{40}Ar used to determine the ages of rocks and minerals on geological time scales.

Argon–argon dating. A variant of the K–Ar dating method fundamentally based on the natural radioactive decay of ^{40}K to ^{40}Ar , but which uses an artificially generated isotope of argon (^{39}Ar) (produced through the neutron irradiation of naturally occurring ^{39}K) as a proxy for ^{40}K .

K–Ar Dating

The potassium–argon (K–Ar) geochronological method is one of the oldest absolute dating methods and is based upon the occurrence of a radioactive isotope of potassium (^{40}K), which naturally decays to a stable daughter isotope of argon (radiogenic ^{40}Ar , also known as $^{40}\text{Ar}^*$). For this reason, the K–Ar method is one of the few radiometric dating techniques in which the parent (^{40}K , a solid) is a different phase from the daughter (^{40}Ar , a gas). The method was first suggested by Goodman and Evans (1941) and one of the earliest K–Ar ages was published by Smits and Gentner (1950). Because potassium is a major or minor element in many minerals, the K–Ar dating technique has been used to date a diverse range of rock types. A comprehensive and detailed overview of the method can be found in Dalrymple and Lanphere (1969).

The conventional K–Ar method became widely used soon after its development and can give reliable ages on many rapidly cooled rocks (e.g., volcanics, dykes). There are, however, a number of limitations with respect to the interpretation of K–Ar ages (further discussed below) which has led to a very limited use of the K–Ar method in current studies. These limitations are largely overcome by the Ar–Ar method, however, which has now superseded the K–Ar method as the geochronological method of choice in dating K-bearing minerals and is further described below.

*Email: jim.lee@queensu.ca

Types of Materials Which Can Be Dated

Any potassium-bearing solid material has the potential to be dated by either the K–Ar or Ar–Ar methods. Because many common rock-forming minerals contain K, the Ar–Ar method is one of the most commonly employed geochronological techniques in many geological studies. The most common materials that are particularly well suited to dating using the K–Ar or Ar–Ar technique include:

K-feldspar	Biotite	Phlogopite	Glasses (e.g., tektites)
Plagioclase	Muscovite	Nepheline	Clays and slates
Hornblende	Sericite	Alunite	Basalts

In general, it should be noted that pure, unaltered minerals yield the best results.

Clays and materials composed of very small grains can be problematic in Ar–Ar dating, depending on their grain size. If the grain size is smaller than about 1 μm , an experimental effect known as “ ^{39}Ar recoil” associated with the neutron irradiation of the sample can make the interpretation of the results difficult; this is further discussed below. For this reason, K–Ar dating may remain the preferred method of dating clays and very fine-grained K-bearing minerals.

Natural Isotopic Abundances

Potassium has three naturally occurring isotopes with the following natural abundances: ^{39}K (93.2581 %), ^{40}K (0.01167 %), and ^{41}K (6.7302 %) (Steiger and Jäger 1977). Of these three isotopes, only ^{40}K is radioactive.

Argon also has three naturally occurring isotopes with the following natural abundances: ^{36}Ar (0.337 %), ^{38}Ar (0.063 %), and ^{40}Ar (99.6 %) (Nier 1950; Steiger and Jäger 1977). Although all three isotopes are stable, ^{40}Ar is the only isotope that is also a radiogenic daughter product (resulting from the decay of ^{40}K). From these abundances, the atmospheric ratio of $^{40}\text{Ar}/^{36}\text{Ar}$ [often denoted as $(^{40}\text{Ar}/^{36}\text{Ar})_{\text{a}}$] is thus 295.5. This ratio is required in the calculation of ^{40}Ar – ^{39}Ar ages, as explained below.

Radioactive Decay Scheme

The K–Ar method is unique among geochronological schemes because the radioactive parent (^{40}K) undergoes a complex branched radioactive decay to both radiogenic ^{40}Ca and ^{40}Ar (Fig. 1).

The dominant mode of decay (89.5 % of the time) is the emission of a β -particle leading to the formation of radiogenic ^{40}Ca . However, ^{40}K can also decay via one of three other modes to radiogenic ^{40}Ar . The most common mode is via electron capture; this may result in the formation of ^{40}Ar in an excited state that subsequently drops to the ground state with the additional release of a γ -ray (10.3 % of the time) or, less commonly, may directly form at the ground state (0.16 % of the time). A very rare mode of decay to ^{40}Ar (only 0.001 % of the time) resulting from the emission of a positron (β^+) has also been hypothesized.

The most widely used set of decay constants for ^{40}K is published by Steiger and Jäger (1977): $\lambda_{\beta^-} = 4.962 \times 10^{-10} \text{ a}^{-1}$ and $\lambda_{\text{e}} + \lambda_{\beta^+}$ (all other branches combined) = $0.581 \times 10^{-10} \text{ a}^{-1}$ for a total decay constant of $\lambda = 5.543 \times 10^{-10} \text{ a}^{-1}$. Thus, the corresponding half-life of ^{40}K is $\ln 2/\lambda = 1,250 \text{ Ma}$.

Fig. 1 ^{40}K decay scheme (After McDougall and Harrison 1999), based on the decay constants of Steiger and Jäger (1977)

High-resolution geochronological studies integrating data from different isotopic systems (e.g., the timing of mass extinctions, the geological time scale) have generated widespread renewed interest throughout the geochronological community in the accuracy and precision of the ^{40}K decay constants ($\lambda = \lambda_e + \lambda_\beta$) due to the existence of small but statistically significant age discrepancies of same precisely dated events by the K–Ar and U–Pb systems. Renne et al. (1998) first noted an ~2.1 % discrepancy between the value of λ_e used by geologists and that used by nuclear physicists – a potential source of systematic error. Min et al. (2000) statistically evaluated the nuclear physics database as well as estimated the total decay constant λ as calibrated with U–Pb and historical dating; their findings led them to suggest tentative values for λ which differ from the currently used value by –1.4 % to –3.1 %, leading to an international call for an improved set of all geochronological decay constants (Begemann et al. 2001). After a careful intercalibration of the widely used Fish Canyon sanidine (FCs) standard with primary K–Ar standards, Jourdan and Renne (2007) stated that there was an imminent need for the revision of the ^{40}K decay constant λ , particularly in the electron-capture branch (i.e., to ^{40}Ar). Kuiper et al. (2008) published a unique study indirectly recalibrating λ by dating sanidine from very precisely dated, astronomically tuned ash beds; their revised estimate of λ brings into synchronicity the Ar–Ar and U–Pb ages of a number of globally significant geological events (e.g., K–T and P–Tr boundaries). Recently, Renne et al. (2010) used a Monte Carlo optimization methodology of all available ^{40}K activity data and integrated ^{238}U – ^{206}Pb and ^{40}Ar – ^{39}Ar data pairs to estimate an optimal λ and corresponding uncertainties. Despite these advances, however, a common set of updated K decay constants has yet to be agreed upon and adopted by the global scientific community.

K–Ar Age Equation

From first principles, it can be shown that the K–Ar age equation is

$$t = \frac{1}{\lambda} \ln \left(\frac{\lambda}{\lambda_e} \cdot \frac{{}^{40}\text{Ar}^*}{{}^{40}\text{K}} + 1 \right) \quad (1)$$

where $t = \text{age}$, $\lambda_e = 0.581 \times 10^{-10} \text{ a}^{-1}$, $\lambda = 5.543 \times 10^{-10} \text{ a}^{-1}$, and ^{40}K and $^{40}\text{Ar}^*$ are the number of atoms (e.g., moles) of each element, respectively. Note that the asterisk (*) in $^{40}\text{Ar}^*$ is used by convention in the literature to denote radiogenic ^{40}Ar (i.e., derived from the radioactive decay of ^{40}K in the same sample), as opposed to ^{40}Ar from other sources, such as the atmosphere (often denoted as $^{40}\text{Ar}_a$) or excess Ar from the Earth's crust or mantle (sometimes denoted as $^{40}\text{Ar}_E$).

Thus, in order to calculate a K–Ar age [which is directly proportional to the $^{40}\text{Ar}^*/^{40}\text{K}$ ratio according to Eq. (1)], one must determine both the $^{40}\text{Ar}^*$ and ^{40}K in the sample.

Ar–Ar Dating

Ar–Ar dating was introduced in the mid-1960s, with the publication of a landmark paper by Merrihue and Turner (1966). The most comprehensive and detailed overview of all aspects of the method can be found in McDougall and Harrison (1999) although some of the data interpretation sections tend to reflect author biases. Dickin (2005) also provides a more concise summary of the technique.

The Ar–Ar method is fundamentally based on the K–Ar method. However, instead of directly measuring ^{40}K , the sample is placed in a nuclear reactor and bombarded with fast neutrons (having energies $>0.1 \text{ MeV}$) to transform a proportion of the potassium (specifically, the fraction associated with ^{39}K) to another isotope of argon, ^{39}Ar . The process results in the addition of the neutron (n) to the ^{39}K nucleus, resulting in the ejection of a proton (p) and energy in a process that can be summarized as follows:

Equation (2) can also be written in the abbreviated form $^{39}\text{K}(n, p)^{39}\text{Ar}$. ^{39}Ar produced in this way is commonly designated as $^{39}\text{Ar}_K$ denoting the fact that it was derived from the neutron irradiation of K. Because $^{39}\text{Ar}_K$ is not a naturally occurring argon isotope, it is directly proportional to the amount of ^{39}K (and hence ^{40}K , because the natural abundances of the K isotopes are known, i.e., the ^{39}K – ^{40}K ratio is known and constant, as stated above) in the sample. Thus, ^{39}Ar serves as an effective proxy for ^{40}K (and therefore, the $^{40}\text{Ar}^*/^{39}\text{Ar}_K$ ratio is directly proportional to the $^{40}\text{Ar}^*/^{40}\text{K}$ ratio).

Ar–Ar Age Equation

The $^{40}\text{Ar}/^{39}\text{Ar}_K$ ratio cannot be directly substituted for the $^{40}\text{Ar}^*/^{40}\text{K}$ ratio in Eq. (1) because the amount of ^{39}Ar generated from the neutron irradiation will clearly be a function of the amount of ^{39}K in the sample, the duration of the irradiation, the neutron flux, and the proportion of fast neutrons within the neutron flux, i.e.,

$$^{39}\text{Ar}_K = ^{39}\text{K} \Delta \int_E \phi(E) \sigma(E) dE = ^{40}\text{K} \left(\frac{^{39}\text{K}}{^{40}\text{K}} \right)_{ab} \Delta \int_E \phi(E) \sigma(E) dE \quad (3)$$

where Δ is the duration of the irradiation, $\phi(E)$ is the neutron flux at energy E , $\sigma(E)$ is the neutron

capture cross section at energy E for the conversion reaction described in Eq. (2), and $(^{39}\text{K}-^{40}\text{K})_{\text{ab}}$ is the $^{39}\text{K}-^{40}\text{K}$ ratio from the natural atomic abundances.

Substitution of Eq. (3) into Eq. (1) thus yields

$$t = \frac{1}{\lambda} \ln \left(\frac{\lambda}{\lambda_e} \cdot \frac{{}^{40}\text{Ar}^*}{{}^{39}\text{Ar}_{\text{K}}} \left[\left(\frac{{}^{39}\text{K}}{{}^{40}\text{K}} \right)_{\text{ab}} \Delta \int_E \phi(E) \sigma(E) dE \right] + 1 \right) \quad (4)$$

The determination of the neutron irradiation parameters in Eq. (4) is not trivial and will vary for each irradiation. Therefore, the Ar–Ar age determination can be greatly simplified if an age standard (sometimes called a monitor mineral) is used. If the age of the standard is known (designated as t_s), then Eq. (4) becomes

$$t_s = \frac{1}{\lambda} \ln \left\{ \frac{\lambda}{\lambda_e} \cdot \left(\frac{{}^{40}\text{Ar}^*}{{}^{39}\text{Ar}_{\text{K}}} \right)_s \left[\left(\frac{{}^{39}\text{K}}{{}^{40}\text{K}} \right)_{\text{ab}} \Delta \int_E \phi(E) \sigma(E) dE \right] + 1 \right\} \quad (5)$$

Common practice is to gather all of the constant terms to define an irradiation parameter J , where

$$J = \frac{\lambda}{\lambda_e} \cdot \left(\frac{{}^{39}\text{K}}{{}^{40}\text{K}} \right)_{\text{ab}} \Delta \int_E \phi(E) \sigma(E) dE \quad (6)$$

so that substitution into Eq. (5) yields

$$t_s = \frac{1}{\lambda} \ln \left\{ J \left(\frac{{}^{40}\text{Ar}^*}{{}^{39}\text{Ar}_{\text{K}}} \right)_s + 1 \right\} \quad (7)$$

or rearranging,

$$J = \frac{e^{\lambda t_s} - 1}{({}^{40}\text{Ar}^*/{}^{39}\text{Ar}_{\text{K}})_s} = \frac{e^{\lambda t_u} - 1}{({}^{40}\text{Ar}^*/{}^{39}\text{Ar}_{\text{K}})_u} \quad (8)$$

However, for a sample of unknown age (herein designated by the subscript u), we obtain from Eq. (7) an analogous age equation for the unknown:

$$t_u = \frac{1}{\lambda} \ln \left\{ J \left(\frac{{}^{40}\text{Ar}^*}{{}^{39}\text{Ar}_{\text{K}}} \right)_u + 1 \right\} \quad (9)$$

Thus, by substituting Eq. (8) into Eq. (9), we obtain the Ar–Ar age equation:

$$t_u = \frac{1}{\lambda} \ln \left\{ \frac{({}^{40}\text{Ar}^*/{}^{39}\text{Ar}_{\text{K}})_u}{({}^{40}\text{Ar}^*/{}^{39}\text{Ar}_{\text{K}})_s} (e^{\lambda t_s} - 1) + 1 \right\} \quad (10)$$

This equation can be compared with the K–Ar age equation [Eq.(1)]. Significantly, this shows that an age standard must always be irradiated with an unknown sample.

Sample Preparation

Sample preparation for both K–Ar and Ar–Ar dating is generally similar. In both cases, the most important criterion is the use of fresh, unaltered samples which are free of inclusions or other contaminants. Also, it is essential to know the geological context of the minerals to be dated so thin-section petrography of the sample to be dated should be the first step. Where aliquots of a mineral are required, rock samples are usually crushed to the grain size of the minerals to be dated. After sieving and ultrasonic washing in acetone and distilled water, mineral separates are obtained through standard techniques, such as the use of magnetic separators or heavy liquids. Ultrapure mineral separates are required because even a small amount of impurities or other minerals can contaminate an argon analysis. As a result, mineral separates are usually inspected carefully under a binocular microscope and only pristine grains (i.e., free from inclusions, defects, or other mineral contaminants) are retained. In this way, mineral separates with >99.9 % purity can be obtained.

The application of lasers in Ar–Ar dating has greatly simplified the sample preparation process. Because much less sample is required, e.g., single crystals are often analyzed, mineral separation can be relatively quick. Furthermore, the use of lasers as age microprobes has allowed the analysis of minerals in situ, typically in a polished thick (100–200 μm) section.

In Ar–Ar dating, the samples to be dated (either single crystals, aliquots of crystals, or a thick section) are commonly wrapped in Al foil or encapsulated in silica tubes, along with the age standard, and then irradiated in a nuclear reactor. The age of a suitable standard and the optimum duration of irradiation should all be carefully considered at this stage. More details can be found in McDougall and Harrison (1999).

Analytical Methods

The following is a general summary of the analytical methods employed in both K–Ar and Ar–Ar dating. Detailed descriptions of the methodology for each dating technique can be found in Dalrymple and Lanphere (1969) and McDougall and Harrison (1999), respectively.

Potassium

The analysis of potassium typically involves wet-chemical or physical methods.

Most K–Ar studies in the early literature employed the use of flame photometry to determine K concentration, which is based on the fact that all elements emit characteristic photons when excited electrons drop back to their ground state. In general, the rock or mineral is dissolved in acid and unwanted elements (such as Si) are removed through a variety of chemical reactions. By heating the potassium-enriched solution with a gas–air flame, measurement of the distinct photon wavelengths emitted by the excited electrons will distinguish the various elements, and the measurement of the intensity of the radiation is directly proportional to the amount of the element in the sample. Unknown samples are calibrated by also analyzing standard solutions of various (known) potassium concentrations and by adding an internal alkali metal standard (typically Li) to the unknown solution. Uncertainties are typically on the order of ± 1 %.

Other analytical methods that have been used less frequently to measure K concentrations include atomic absorption spectroscopy, based on the absorption of radiant energy by potassium atoms, which produce an absorption spectrum characteristic of that element; X-ray fluorescence, based on the X-ray emission spectrum of potassium resulting from bombarding the sample with an X-ray beam; neutron activation, in which an artificial unstable isotope of K (^{42}K) is created by irradiating

the sample with neutrons to convert ^{41}K and its subsequent γ -decay is measured; and isotope dilution, in which a known quantity of an isotopic tracer (known as a “spike,” typically ^{41}K) is added to the unknown solution before measuring all of the K isotopes in a solid-source mass spectrometer.

Argon

Argon in both K–Ar and Ar–Ar dating is measured in a two-step process typically involving extraction and purification from the mineral sample and then measurement and calculation of the $^{40}\text{Ar}^*$. Because argon is a gas, the easiest way to extract argon is to fuse the sample at high temperature. This is usually done in a high-vacuum system using a radio-frequency (induction) or resistance furnace or a laser (in Ar–Ar dating only). Because other gases, such as N_2 , O_2 , or CO_2 , can also be released, the argon is purified through the use of liquid nitrogen traps, Zr-alloy getters, and Ti sponges. The purified argon is then analyzed in an ultrahigh vacuum system in a noble gas mass spectrometer. Simply, the argon that enters the mass spectrometer is first ionized in the ion source. The resultant beam of positive Ar ions is collimated and then accelerated through both electric and magnetic fields that separate the beam into a series of beams that follow a curved flight path, each with a distinct charge/mass ratio. Older mass spectrometers had only a single detector to measure the incoming beam current (proportional to the number of Ar atoms), but latest-generation mass spectrometers now have multicollector capability.

In K–Ar dating, because $^{40}\text{Ar}^*$ and ^{40}K must be measured separately, a method is required to determine the absolute concentration of $^{40}\text{Ar}^*$ in the unknown sample. The most widely used method is by isotope dilution. In this method, a known quantity of an argon tracer (also called a “spike”) is mixed with the argon from the unknown sample. The distinguishing characteristic of the spike is that it must have a known argon isotopic composition, i.e., the ratio of ^{36}Ar – ^{38}Ar – ^{40}Ar , different to the natural abundance of these isotopes. Since the isotopic composition of the mixture can be measured in the mass spectrometer and the argon isotopic composition and amount of spike are known, it is then possible to calculate the isotopic composition and amount of the argon from the unknown. Argon tracers are typically enriched in ^{38}Ar , and all three naturally occurring argon isotopes (^{36}Ar , ^{38}Ar , and ^{40}Ar) are measured in the mass spectrometer. Dalrymple and Lanphere (1969) describe the isotope dilution process in more detail.

In Ar–Ar dating, only the ratio of two argon isotopes ($^{40}\text{Ar}^*$ and $^{39}\text{Ar}_\text{K}$) is required in the age equation [Eq. (10)], so the argon analysis is, in principle, much simpler than in K–Ar dating because absolute concentrations are not required. However, because of neutron-induced interference reactions (described below), five argon isotopes (^{36}Ar , ^{37}Ar , ^{38}Ar , ^{39}Ar , and ^{40}Ar) must be measured.

Data Corrections

There are several important corrections that must be applied to the raw data in order to calculate an accurate age.

Blank Correction

Although argon is measured in an ultrahigh vacuum environment in both K–Ar and Ar–Ar dating, system blanks from both the extraction line and mass spectrometer must be subtracted from the total amount of each argon isotope measured.

Atmospheric Correction

This is the most fundamental correction in both K–Ar and Ar–Ar dating. Because ^{40}Ar is the most abundant isotope of argon in the atmosphere, it can be adsorbed onto the surface of mineral grains or analytical equipment or can be incorporated into minerals during crystallization, so a correction must be made to subtract this atmospheric component ($^{40}\text{Ar}_a$) from the total amount of ^{40}Ar measured. Since it is impossible to distinguish $^{40}\text{Ar}_a$ from $^{40}\text{Ar}^*$, another isotope of argon present in the atmosphere ($^{36}\text{Ar}_a$) is also measured in the mass spectrometer. Since the atmospheric ratio ($^{40}\text{Ar}/^{36}\text{Ar}$)_a is 295.5, the atmospheric ^{40}Ar component is easily calculated as $^{40}\text{Ar}_a = 295.5 \times ^{36}\text{Ar}_a$. Depending on the age of the sample or the amount of gas being measured, this correction can be significant, e.g., for young samples or samples with very low K.

Neutron-Induced Interferences

In Ar–Ar dating, neutron bombardment of most minerals generates numerous reactions with elements other than K that produce a variety of argon isotopes. These neutron-induced interferences must therefore be corrected in order to obtain accurate ages. The most important reactions are [cf. Eq. (2)] $^{40}\text{Ca}(n, n\alpha)^{36}\text{Ar}$, $^{40}\text{Ca}(n, \alpha)^{37}\text{Ar}$ (^{37}Ar is radioactive and decays to ^{37}Cl with a half-life of 35.1 days), $^{37}\text{Cl}(n, \gamma)^{38}\text{Cl} \rightarrow ^{38}\text{Ar}$ (^{38}Cl is radioactive and decays to ^{38}Ar with a half-life of 37.3 min), $^{42}\text{Ca}(n, \alpha)^{39}\text{Ar}$, $^{39}\text{K}(n, p)^{39}\text{Ar}$, and $^{40}\text{K}(n, p)^{40}\text{Ar}$. From these reactions, it can be seen that neutron-induced interferences will affect the measurement of five argon isotopes (^{36}Ar , ^{37}Ar , ^{38}Ar , ^{39}Ar , and ^{40}Ar) and are the reason why all of these isotopes must be measured. McDougall and Harrison (1999) describe in detail the added complexities in the data correction process resulting from neutron irradiation in Ar–Ar dating.

Radioactive Decay Correction

In Ar–Ar dating, two of the artificial argon isotopes produced by neutron irradiation ($^{37}\text{Ar}_{\text{Ca}}$ and $^{39}\text{Ar}_{\text{K}}$) are themselves radioactive with half-lives that are on a time scale of days to years. $^{37}\text{Ar}_{\text{Ca}}$ has a half-life of about 35.1 days and $^{39}\text{Ar}_{\text{K}}$ has a half-life of 269 years (Stoerner et al. 1965), so further corrections for the time interval between neutron irradiation and analysis in the laboratory must also be made.

Modes of Analysis

Conventional (Total Fusion) Age

The analysis of a sample in conventional K–Ar dating produces a single age, since the sample must be completely dissolved and fused in order to extract the ^{40}K and ^{40}Ar , respectively. The analogous process (total fusion) can be performed in the Ar–Ar analysis of a sample to yield a single, total fusion age. Because of the decreased sensitivity of early-generation mass spectrometers, several milligrams of purified mineral separates often had to be analyzed to obtain enough argon to calculate an age. Improved sensitivity of current-generation mass spectrometers now permits the Ar–Ar analysis of single crystals which can be fused with either a furnace or a laser. In fact, lasers can be used as age microprobes to obtain intragrain Ar–Ar age analyses, in which a small amount of material can be ablated by the laser within a mineral grain and yields a total fusion age for that spot. Ar–Ar laser microprobes thus permit the direct determination of the ^{40}Ar (age) distribution within single crystals. For more information about single-crystal laser dating, see the entry “► [Single-Crystal Laser Fusion](#).”

Ar–Ar Step-Heating

Because the Ar–Ar method only requires the extraction of gaseous argon isotopes, Merrihue and Turner (1966) noted that the sample did not have to be fused in a single step, but could be incrementally heated in steps of increasing temperature, and the argon isotopes extracted during each temperature step could be analyzed to yield an age for that step. This incremental-heating (or step-heating) technique thus was a major advantage over conventional K–Ar dating because it provided a way to examine the distribution of ^{40}Ar (and hence, ages) within minerals. The fundamental principle is based on solid-state diffusion theory and is illustrated in Fig. 2.

Consider a homogeneous spherical mineral grain. If the grain is heated at a relatively low temperature (T_1) for a finite period of time, the argon isotopes diffusing out of the grain can only come from a thin region (i.e., shell) along the boundary of the grain and will yield an age t_1 associated with that region. If the grain is now heated at a slightly higher temperature (e.g., $T_2 > T_1$) for the same length of time, the argon isotopes will diffuse from a spherical region that extends slightly deeper into the grain and will yield an age t_2 . In this way, successively higher steps of increasing T will sample regions deeper and deeper into the grain until the highest temperature steps (e.g., T_9) will sample the argon from the grain core. The age of each step is commonly referred to as an apparent age because it may not necessarily be identical to the overall age of the mineral grain.

By plotting the apparent ages of each of the steps (t_1 – t_9) in a diagram of apparent age versus the cumulative fraction of $^{39}\text{Ar}_\text{K}$ released, a so-called apparent age spectrum can be constructed. For example, consider the same spherical grain in Fig. 2. If ^{39}K is homogeneous throughout the grain (i.e., K is not chemically zoned), then the $^{39}\text{Ar}_\text{K}$ produced from the fast-neutron irradiation of the ^{39}K should also be uniformly distributed throughout the grain from core to rim. If the ^{40}Ar distribution is uniform throughout the grain, then ^{40}Ar – $^{39}\text{Ar}_\text{K}$ ratio (and thus, apparent age) should be identical for every step (t_1 – t_9) and the resultant apparent age spectrum yields a “plateau” age (Fig. 3). The significance of a plateau age is discussed in the following section.

Fig. 2 Hypothetical spherical grain subject to step-heating. By heating the grain in incremental steps of increasing temperature, argon (and hence, the age distribution within the grain) can be sampled progressively from the grain boundary at the lowest temperature (T_1 – dark blue) to the grain core at the highest temperature (T_9 – red)

Fig. 3 Apparent age spectrum for a hypothetical grain with a uniform distribution of ^{40}Ar and $^{39}\text{Ar}_K$ throughout the grain. The horizontal length of each step corresponds to the fraction of $^{39}\text{Ar}_K$ from the total $^{39}\text{Ar}_K$ released and the vertical width corresponds to the apparent age and corresponding age uncertainty of that step (in this example, $\pm 2\sigma$). The color for each step corresponds to the region of the mineral grain in Fig. 2 from which the age of that step is derived. The weighted mean age from all of the steps yields an “integrated” age for the sample, which is equivalent to the age that would have been obtained if the sample was fused in a single step. If a significant fraction of the age spectrum (typically $>50\%$) is composed of steps having identical ages within error, then the weighted mean age of those steps is said to define a plateau age

Ar–Ar Data Interpretation

Because argon is a noble gas, its mobility within crystals is strongly dependent on temperature. Thus, the interpretation of Ar–Ar age spectra is based primarily on solid-state (volume) diffusion theory.

Plateau Ages

There is no convention that is widely accepted by the geochronology community as a standard definition of a plateau in an Ar–Ar age spectrum. Thus, the definition of a plateau should be explicitly stated where ambiguity may result. Common elements in any definition of a plateau generally include a series of contiguous steps which overlap within error and which comprise a significant fraction of the $^{39}\text{Ar}_K$ released from the sample. For example, the Fleck et al. (1977) definition states that a plateau is defined by three or more contiguous steps comprising at least 50 % of the $^{39}\text{Ar}_K$ released which overlap at the 2σ level. The plateau age is calculated as the weighted mean of the ages of all steps included in the plateau, with the inverse of the variance of the age of each step used as the weights. Examples of plateau age spectra are shown in Figs. 3–5.

The existence of a plateau is, in general, interpreted to indicate a uniform distribution of $^{40}\text{Ar}^*$ within that region of the mineral grain(s) sampled by those steps, and thus, a plateau age is often considered to be geologically meaningful. Understanding the geological context of the dated sample is critical in accurately interpreting a plateau age, however, because of argon’s ability to diffuse under elevated temperature conditions. For example, if the dated sample comes from a rapidly cooled igneous dyke which has undergone no metamorphism since intrusion, the plateau age may represent the actual formation age of the dyke. If the dated sample comes from a metamorphosed rock, however, the plateau age may represent the age of metamorphism rather than the protolith age, if the rock has been reheated to a temperature high enough for any accumulated argon to diffuse out of the mineral at the time of metamorphism, effectively “resetting” the Ar–Ar age of the mineral.

Fig. 4 Ar–Ar age spectrum exhibiting an argon-loss profile as defined by steps 1–3. Note that steps 4–9 still define a plateau with an age of ~23.6 Ma

Fig. 5 Ar–Ar age spectrum exhibiting an excess-argon profile as defined by steps 1–3. Note that steps 4–9 still define a plateau with an age of ~23.6 Ma

An added complication in interpreting plateau ages arises in the step-heating of hydrous minerals such as amphiboles and micas. Gaber et al. (1988), Lee et al. (1991), Sletten and Onstott (1998), and Lo et al. (2000) found that during an Ar–Ar experiment, hydrous minerals may not remain stable at elevated temperatures due to oxidation and dehydroxylation of the crystal structure while being step-heated in vacuo. This structural decomposition of the crystal can lead to the formation of numerous extended defects throughout the grains and result in the homogenization of argon gradients which could lead to the generation of an apparent plateau (i.e., a pseudo-plateau) which has no geological significance. Thus, the plateau ages from such samples should be interpreted with caution.

Ar Loss

There are three main scenarios in which an age spectrum showing apparent Ar loss can be generated. The first is due to reheating. If a mineral has experienced a moderate–high T geological event, such as proximity to an igneous intrusion, contact metamorphism, hot fluid flow, etc., argon can diffuse out of the mineral. If argon diffusion is not sustained for protracted periods of time, it is possible that the mineral may experience only partial argon loss, such that argon is lost from a limited region of the grain nearest the grain boundary and the original argon is retained in the grain core. In this case, an apparent age spectrum may look like that in Fig. 4. A second scenario involves slow regional

cooling. If a mineral is subject to slow cooling resulting from regional-scale metamorphism or exhumation, partial argon loss can occur over long periods of time if the rate of cooling is not rapid enough to retard Ar diffusion. This will also yield an age spectrum similar to Fig. 4. Finally, a third scenario involves impurities (e.g., inclusions) in the analyzed crystals, which often degas in the lower T steps and can cause an apparent Ar-loss profile. Fortunately, it is often possible to determine if impurities are the cause by examining other argon isotopes (see section “Ca/K and Cl/K Spectra” below). Therefore, knowledge of the sample and its local geological context is important in interpreting such age spectra.

Excess ^{40}Ar

Thermal activation can also result in the diffusion of ^{40}Ar from the external environment into mineral grains, if the chemical potential of argon (often referred to as the argon partial pressure) is much greater outside the crystal than inside. Because this ^{40}Ar is not associated with the in situ decay of ^{40}K (i.e., radiogenic $^{40}\text{Ar}^*$), it is commonly referred to as excess Ar ($^{40}\text{Ar}_\text{E}$). There are many possible sources of excess Ar. One source is the host rock itself; if there are K-bearing minerals, local thermal reheating can release some of the $^{40}\text{Ar}^*$ to the surroundings, where it then becomes $^{40}\text{Ar}_\text{E}$. Another common source is hot Ar-rich fluids which may carry $^{40}\text{Ar}_\text{E}$ from the lower crust or distal regions. Incorporation of $^{40}\text{Ar}_\text{E}$ from the external environment means that age spectra tend to have anomalously old ages in the lower T steps (Fig. 5).

Sometimes, anomalously old ages are reflected in the highest T steps. Although the reasons for this will vary from sample to sample, one potential source is $^{40}\text{Ar}_\text{E}$ released from contaminant phases (e.g., pyroxene). Such phases may only release excess argon at high T or the phases may occur as internal inclusions which can only degas when the host mineral itself decomposes at high T . An example of an age spectrum displaying excess argon in the low and high T steps is shown in Fig. 6. An excellent review of the role of excess Ar in Ar–Ar dating may be found by Kelley (2002).

^{39}Ar Recoil

When a fast neutron interacts with a ^{39}K nucleus to form ^{39}Ar during neutron irradiation, there is a recoil energy also associated with this process. Turner and Cadogan (1974) calculated that the average recoil distance which an ^{39}Ar atom can move from the original position of the ^{39}K atom is $\sim 0.08\ \mu\text{m}$, which has been subsequently confirmed by direct experiment (Villa 1997). Although the ^{39}Ar recoil distance is very short compared to the length scale of most mineral grains (and therefore,

Fig. 6 Ar–Ar age spectrum exhibiting an excess-argon profile in the low and high T steps. This is sometimes referred to as a “saddle-shaped” age spectrum

will have a negligible effect in such cases), it can have a significant effect for very fine-grained materials (e.g., 1 μm) or samples with μm -scale domains, where the length scale of argon diffusion is of the same order of magnitude. In particular, it has been shown that significant ^{39}Ar loss can occur in minerals such as clays since it can be recoiled entirely out of the crystal structure (e.g., Halliday 1978). This has led to the development of encapsulation techniques when performing ^{40}Ar – ^{39}Ar dating on such fine-grained minerals, in which the sample is placed in a vacuum-evacuated, sealed capsule before irradiation in order to capture the ejected ^{39}Ar , which can then be measured subsequently in the mass spectrometer by breaking the capsule in vacuo and then reintegrating the measured ^{39}Ar trapped in the capsule into the step-heating results (e.g., Dong et al. 1995, 1997).

Alternatively, the recoiled ^{39}Ar may not be lost to the surrounding “void” but may become tightly imbedded in an adjacent K-poor phase. This is illustrated in Fig. 7.

For example, Huneke and Smith (1974) and Lo and Onstott (1989) observed this phenomenon occurring between a K-rich phase and olivine and biotite and chlorite, respectively. In such cases, the resultant age spectrum can display anomalously high ages in the low T steps (reflecting the loss of ^{39}Ar recoiled near the grain boundary) monotonically decreasing to anomalously low ages in the high T steps as the ^{39}Ar is degassed from the K-poor phases. Such an age spectrum is shown in Fig. 8.

For this reason, Ar–Ar studies involving fine-grained samples must interpret the results with care. In such specific situations, it may also be worthwhile to consider using conventional K–Ar dating, which avoids such difficulties.

Fig. 7 ^{39}Ar recoil. Recoil energy from the fast-neutron conversion of ^{39}K can either eject ^{39}Ar atoms or reimplant them in adjacent phases, where they can be liberated at high temperature during a step-heating experiment

Fig. 8 Ar–Ar age spectrum exhibiting the effects of ^{39}Ar recoil artifacts. Anomalously high ages are seen in the first few steps which gradually decline to anomalously low ages in the final few steps

Fig. 9 (a) Ca/K spectrum showing elevated Ca/K ratios in the first three steps in comparison to the remaining steps. (b) Cl/K spectrum showing lower Ca/K ratios in the first three steps in comparison to the remaining steps. These spectra correspond to the same sample analyzed in Fig. 4. Such spectra can be useful in interpreting degassing patterns in Ar–Ar step-heating experiments

Ca/K and Cl/K Spectra

One useful aspect about the ^{40}Ar – ^{39}Ar technique is that it has the ability to yield significant information about the chemical composition of the samples that are being dated. The foundation of the ^{40}Ar – ^{39}Ar technique (through the $^{39}\text{K}(\text{n},\text{p})^{39}\text{Ar}$ reaction) already provides chemical information on the K content in the sample. As noted in the section on Data Corrections, however, there are also other neutron-induced interferences, leading to the production of ^{37}Ar from ^{40}Ca and ^{38}Ar from ^{37}Cl . Thus, an ^{37}Ar – ^{39}Ar ratio is directly related to a Ca/K ratio and an ^{38}Ar – ^{39}Ar ratio is directly related to a Cl/K ratio. Examples of Ca/K and Cl/K spectra are shown in Fig. 9.

These argon isotope ratios can provide useful information on the degassing of phases during a step-heating run. For example, consider Figs. 4 and 9. These spectra were all derived from the same sample, and a comparison of the first three steps in all of the spectra shows that the apparent argon-loss profile in Fig. 4 actually corresponds to argon released from a high Ca/K, low Cl/K reservoir, in contrast to a reservoir which has a uniform Ca/K and Cl/K over the steps corresponding to the plateau. This strongly suggests that the first three steps showing apparent argon-loss profile do not necessarily reflect a geologically meaningful event, but rather likely reflect argon released from a small amount of a contaminating phase, such as plagioclase or epidote. Note that this also does not necessarily affect the validity of the plateau age, but rather helps to discern the geological significance of various portions of an apparent age spectrum. A very illustrative study demonstrating the use of Ca/K spectra coupled with electron microprobe analyses to interpret a complex age spectrum is by Hanes et al. (1985).

Isochron Diagrams

The total amount of ^{40}Ar measured by a mass spectrometer during the analysis of an unknown for both K–Ar and Ar–Ar dating is a function of two main sources of ^{40}Ar – radiogenic ^{40}Ar from the in situ decay of ^{40}K in the sample ($^{40}\text{Ar}^*$) and any initial ^{40}Ar from the atmosphere ($^{40}\text{Ar}_i$). In other words,

$$^{40}\text{Ar}_{\text{total}} = ^{40}\text{Ar}_i + ^{40}\text{Ar}^* \quad (11)$$

This is analogous to many other geochronological systems, e.g., initial Sr in Rb–Sr and initial Pb in Pb–Pb. By substituting the K–Ar age equation of Eq. (1) into Eq. (11), we find

$$^{40}\text{Ar}_{\text{total}} = ^{40}\text{Ar}_i + \left(\frac{\lambda_e}{\lambda}\right)^{40}\text{K}(e^{\lambda t} - 1) \quad (12)$$

The difficulty in using Eq. (12) is that it is impossible to know exactly how much $^{40}\text{Ar}_i$ is in the sample, so to get around this, we divide Eq. (12) by stable, non-radiogenic, naturally occurring Ar isotope (^{36}Ar) to get

$$\left(\frac{^{40}\text{Ar}}{^{36}\text{Ar}}\right)_{\text{total}} = \left(\frac{^{40}\text{Ar}}{^{36}\text{Ar}}\right)_i + \left(\frac{\lambda_e}{\lambda}\right)(e^{\lambda t} - 1) \cdot \frac{^{40}\text{K}}{^{36}\text{Ar}} \quad (13)$$

In a plot of ($^{40}\text{Ar}/^{36}\text{Ar}$) versus ($^{40}\text{K}/^{36}\text{Ar}$), Eq. (13) has the form of a straight line $y = mx + b$. Note that the slope $m = (\lambda_e/\lambda)(e^{\lambda t} - 1)$ can therefore be used to determine the age t , and the y -intercept $b = (^{40}\text{Ar}/^{36}\text{Ar})_i$ is often the atmospheric ratio $(^{40}\text{Ar}/^{36}\text{Ar})_a = 295.5$.

In K–Ar dating, several minerals which have varying amounts of K (e.g., amphibole, biotite, and K-feldspar) from a rock sample are usually analyzed and the results are plotted on such a diagram. If the data form a straight line, this is termed a *mineral isochron* and the slope can therefore be used to calculate the age of the sample. An analogous procedure can be used to analyze whole-rock samples across a region, in which case a resultant line would be termed a *whole-rock isochron*. The goodness-of-fit of such lines is usually indicated by the mean square of the weighted deviates (MSWD) (McIntyre et al. 1966; York 1969).

In Ar–Ar dating, we substitute Eq. (9) into Eq. (11) to get

$$^{40}\text{Ar}_{\text{total}} = ^{40}\text{Ar}_i + \frac{(e^{\lambda t} - 1)}{J} \cdot ^{39}\text{Ar}_{\text{K}} \quad (14)$$

and dividing again by a stable, non-radiogenic, naturally occurring Ar isotope (^{36}Ar), we find

$$\left(\frac{^{40}\text{Ar}}{^{36}\text{Ar}}\right)_{\text{total}} = \left(\frac{^{40}\text{Ar}}{^{36}\text{Ar}}\right)_i + \frac{(e^{\lambda t} - 1)}{J} \cdot \frac{^{39}\text{Ar}_{\text{K}}}{^{36}\text{Ar}} \quad (15)$$

This is analogous to the K–Ar isochron equation [Eq. (13)], so in a plot of ($^{39}\text{Ar}/^{36}\text{Ar}$) versus ($^{40}\text{Ar}/^{36}\text{Ar}$), Eq. (15) has the form of a straight line $y = mx + b$. Note that the slope $m = (e^{\lambda t} - 1)/J$ can therefore be used to determine the age t , and the y -intercept $b = (^{40}\text{Ar}-^{36}\text{Ar})_i$ is often the atmospheric ratio $(^{40}\text{Ar}-^{36}\text{Ar})_a = 295.5$. An example of such an isochron diagram is shown in Fig. 10.

One feature of such isochron diagrams in Ar–Ar dating is that there is a strong correlation of uncertainties between the abscissa ($^{39}\text{Ar}-^{36}\text{Ar}$) and ordinate ($^{40}\text{Ar}-^{36}\text{Ar}$), shown by the rotated error ellipses which lie subparallel to the line in Fig. 10. This is a result of the common denominator (^{36}Ar) in each; because ^{36}Ar is such a small peak to measure in relation to ^{40}Ar , the relative uncertainty associated with measuring ^{36}Ar is much larger in relative terms and so this error correlation is significant.

To reduce this large correlation of errors, the inverse isochron (also known as isotope correlation) diagram places the largest measured peak (^{40}Ar) in the denominator.

Dividing Eq. (14) by $^{40}\text{Ar}_{\text{total}}$

Fig. 10 Ar–Ar isochron diagram using the data obtained from the sample shown in Fig. 4. Note that the first three temperature steps do not lie on a line corresponding to the steps defining the plateau. A best-fit line through these steps yields a slope corresponding to an Ar–Ar isochron age of 23.6 Ma, which is identical to the plateau age

$$1 = \frac{{}^{40}\text{Ar}_i}{{}^{40}\text{Ar}_{\text{total}}} + \frac{(e^{\lambda t} - 1)}{J} \left(\frac{{}^{39}\text{Ar}}{{}^{40}\text{Ar}} \right)_{\text{total}} \quad (16)$$

If ${}^{40}\text{Ar}_i = {}^{36}\text{Ar}_i \cdot v$, where v is the initial $({}^{40}\text{Ar}/{}^{36}\text{Ar})_i$ ratio, then

$$1 = \frac{{}^{36}\text{Ar}_i \cdot v}{{}^{40}\text{Ar}_{\text{total}}} + \frac{(e^{\lambda t} - 1)}{J} \left(\frac{{}^{39}\text{Ar}}{{}^{40}\text{Ar}} \right)_{\text{total}} \quad (17)$$

and dividing by v :

$$\left(\frac{{}^{36}\text{Ar}}{{}^{40}\text{Ar}} \right)_{\text{total}} = \frac{1}{v} - \frac{(e^{\lambda t} - 1)}{Jv} \left(\frac{{}^{39}\text{Ar}}{{}^{40}\text{Ar}} \right)_{\text{total}} \quad (18)$$

In a plot of $({}^{39}\text{Ar}/{}^{40}\text{Ar})$ versus $({}^{36}\text{Ar}/{}^{40}\text{Ar})$, Eq. (18) has the form of a straight line $y = mx + b$. Note that in this case, y -intercept $b = 1/v$ is often the inverse of the atmospheric ratio $({}^{40}\text{Ar}-{}^{36}\text{Ar})_a = 1/295.5 = 3.384 \times 10^{-3}$, and the x -intercept (when the ${}^{36}\text{Ar}-{}^{40}\text{Ar}$ equals zero) is simply ${}^{39}\text{Ar}/{}^{40}\text{Ar}^* = J/(e^{\lambda t} - 1)$ from Eq. (8) and therefore yields an *intercept age* t . An example of an inverse isochron diagram is shown in Fig. 11.

The data which form a line on an isotope correlation diagram can be interpreted to reflect mixing between two Ar reservoirs (or components) in the sample. More complex mixing patterns between different argon reservoirs within a crystal may also be discerned using such diagrams (e.g., Phillips and Onstott 1988). Sometimes, Ar–Ar isochron diagrams may be somewhat misleading because nonlinear data may *appear* to have a good linear correlation because of the strong correlation of errors; however, Dalrymple et al. (1988) have shown that there is no difference between isochron versus inverse isochron plots as long as rigorous mathematics for the least squares fitting of lines with correlated errors is used.

Probability Distribution Diagrams

Probability distribution diagrams (Fig. 12) are generally used to plot the cumulative results of a group of single-grain total fusion analyses. Analogous to histograms, the diagrams plot the age on

Fig. 11 Ar–Ar inverse isochron diagram using the data obtained from the sample shown in Fig. 4. Note that the first three temperature steps do not lie on a line corresponding to the steps defining the plateau. A best-fit line through these steps yields an intercept age of 23.6 Ma, which is identical to the plateau age in Fig. 4 and the isochron age in Fig. 10

Fig. 12 Probability distribution diagram of the Ar–Ar ages from 58 single crystals of detrital muscovite derived from a sandstone. The higher the peak, the greater the number of grains of that age. In this example, the muscovite grains appear to be derived from at least three different sources or regions – a dominant source with an age of 880–890 Ma, another source with an age of ~950 Ma, and a third (minor) source with an age of ~1,000 Ma

the x-axis versus the relative probability (i.e., the sum of the normal distributions of the individual analyses of single-grain total fusion ages based on their experimental uncertainties; Deino and Potts 1992). They are particularly useful in detrital provenance studies where source regions of different ages can be distinguished.

Argon Terminology

There are several possible sources of argon in rocks. The following glossary describes these various sources:

Artificially induced Ar – argon (typically ^{36}Ar , ^{37}Ar , ^{38}Ar , ^{39}Ar , or ^{40}Ar) produced in a mineral during fast-neutron irradiation in a nuclear reactor, due to neutron interactions with Cl, Ca, and K.

Atmospheric Ar – argon from the atmosphere, may be either $^{36}\text{Ar}_a$, $^{38}\text{Ar}_a$, or $^{40}\text{Ar}_a$. The present-day $^{40}\text{Ar}_a/^{36}\text{Ar}_a$ is 295.5.

Cosmogenic Ar – any Ar isotope (typically ^{36}Ar , ^{37}Ar , ^{38}Ar , ^{39}Ar , or ^{40}Ar) produced from cosmic ray interactions with various elements (including Ca, Ti, Fe) in a mineral, mainly through spallation reactions, but also through neutron capture, normally only a concern when dealing with extraterrestrial samples.

Excess Ar – any Ar (typically ^{40}Ar) which is incorporated into minerals by processes other than the in situ radioactive decay of ^{40}K in the crystal, includes inherited Ar but may also include Ar derived from physical contamination by other minerals or Ar introduced into a crystal from other sources after its formation, e.g., by metamorphic fluids.

Inherited Ar – argon (typically ^{40}Ar) incorporated into the crystal lattice of a mineral at the time of its formation which is NOT associated with the radiogenic $^{40}\text{Ar}^*$ produced from the in situ decay of ^{40}K in the crystal (see *excess Ar*). This is one form of excess Ar.

Radiogenic Ar – $^{40}\text{Ar}^*$ formed from the in situ decay of ^{40}K in a mineral.

Trapped Ar – argon that is trapped within a rock or mineral at the time of its formation or during a subsequent event, can exist in the crystal lattice (= *inherited Ar*) or as fluid inclusions (which would typically be expected to contain Ar of atmospheric composition for terrestrial samples).

Applications

K–Ar

At present, there are two main uses of the conventional K–Ar method. First, it can be used to calibrate fundamental physical parameters such as the K decay constant, since it is a method grounded on first principles, i.e., the method is completely independent of other geochronological methods. Second, it is well-suited for dating potassium-bearing fine-grained materials (such as clays or glauconites) where ^{39}Ar recoil would be problematic.

In general, however, the method of choice for dating most K-bearing materials in a variety of geological studies is the Ar–Ar method.

Ar–Ar

The presence and abundance of K-bearing minerals in a variety of rocks, coupled with the strong temperature dependence of argon diffusion in minerals, have led to the widespread application of Ar–Ar dating in a variety of geological applications. There are a plethora of studies in each of the general areas below which are far too numerous to list; some illustrative references are included, and more can also be found in more specific entries cross-referenced in this work.

In general, Ar–Ar dating has been applied most often in the following areas of study which are described briefly below.

Refinement of the Geological Time Scale and Time-Scale Boundaries

Ar–Ar dating and U–Pb dating are currently the most commonly used techniques in establishing the timing of geological events that are used to mark the various temporal boundaries in the geological time scale. The accuracy and precision of both of these methods remain unmatched by any other geochronological technique. Ar–Ar dating has been used to refine the age of many boundaries such as the Cretaceous–Paleogene boundary by dating the age of the Chicxulub crater off the coast of Mexico (e.g., Renne et al. 2013) or the Permian–Triassic boundary by dating large-scale flood basalts (e.g., Reichow et al. 2009).

Hominid Evolution

The high precision of the Ar–Ar technique makes it an excellent method in which to date fossil evidence of the earliest origins of the human species. By precisely dating minerals (such as sanidines) from volcanic ash beds which lie above and below fossilized remains, Ar–Ar dating has proven to be extremely useful in understanding the evolution of hominids. Examples of Ar–Ar studies include the dating of hominid evolution in western Africa (e.g., Leakey et al. 1995, 1998), the earliest hominids in Java (Swisher et al. 1994), and early hominids in Georgia (Gabunia et al. 2000), which appear to shift the date of hominid dispersal out of Africa at least half a million years earlier than previously thought. Antón and Swisher (2004) provide a general review of hominid evolution out of Africa, and an overview of the method applied to paleoanthropology and archeology is provided by Deino et al. (1998).

Thermochronology

Because Ar is a noble gas, it is particularly sensitive to temperature. If ambient temperatures are high enough, Ar will preferentially leave the mineral structure via diffusive transfer and escape to the surroundings. Thus, rocks which have been reheated after crystallization (e.g., due to metamorphism) may partially or completely lose Ar from their minerals, depending on the diffusion characteristics of the mineral, the temperature, and the time involved. The temperature dependence of Ar–Ar ages has opened up an entire field of geochronology known as thermochronology where the thermal evolution of rocks and regions can be studied using multiple geochronological techniques; of these, Ar–Ar technique is one of the most versatile.

As mentioned in the section on Modes of Analysis, the interpretation of argon data is fundamentally based on solid-state diffusion theory. There is now a considerable body of knowledge associated with the application of diffusion theory in geochronology, starting with the landmark paper by Dodson (1973), who developed the mathematics defining the concept of *closure temperature* (T_c). This key concept, which is defined as the temperature of a cooling system at the time defined by the age of a mineral, has led to the development of field thermochronology, in which the thermal (i.e., temperature T , time t) histories of rocks and regions can be elucidated with geochronological techniques. Because argon diffuses at different rates in minerals (due to difference in chemical composition and the structure of the crystal lattice), different K-bearing minerals span a different range of Ar closure temperatures. Argon diffusion experiments have determined that, in general, for K-bearing minerals having the same length scale of diffusion (i.e., grain size) and cooling rate, argon closure temperatures increase in the following order: T_c (K-feldspar) < T_c (biotite) < T_c (muscovite) < T_c (hornblende). As a result, studying rocks having these minerals means that an Ar–Ar dating study could elucidate thermal histories over a temperature range of potentially 150–600 °C; this temperature range covers a significant portion of the thermal history of many rocks, making Ar–Ar thermochronology a very powerful tool in the study of the evolution of geological terranes. Complicated numerical models attempting to deconvolute thermal histories from the step-heating of single crystals of K-feldspar have been developed (e.g., the multidiffusion domain (MDD) model of Lovera et al. 1989 and subsequent papers thereafter), but these remain controversial because of a lack of correspondence to actual physical features which are observed in the analyzed minerals, both in nature and during argon step-heating experiments (see Parsons et al. 1999, 2010). The entry on Thermochronology provides more details on the fundamental principles of this field.

Many thermochronological Ar–Ar studies have been conducted throughout the world, spanning most of the Earth's history. One of the earliest Ar–Ar thermochronological studies was by Berger and York (1981), who analyzed hornblende, biotite, plagioclase, and K-feldspar to determine the

cooling history of the Haliburton Highlands in the Grenville Province, Ontario. An overview of many of these studies and a more detailed analysis of thermochronological principles can be found in McDougall and Harrison (1999).

Structural Geology

Ar–Ar dating has found widespread application in solving structural geology problems because it can date K-bearing phases (especially micas) that form during deformational events. Moreover, the development of the laser microprobe in Ar–Ar dating (see “► [Single Crystal Laser Fusion](#)”) enables mineral grains to be dated in situ and, thus, potentially allows multiple deformation events to be dated in a single rock. Many recent studies have also highlighted the importance of considering defect structures associated with deformation in controlling Ar mobility and therefore in interpreting Ar–Ar ages; the study of white micas by Kramar et al. (2001) highlights the utility of the ^{40}Ar – ^{39}Ar laser microprobe in this regard.

Tectonics

The ability to document a significant portion of the low–mid-temperature history of geological terranes has made Ar–Ar dating the method of choice in many tectonic studies. In general, thermochronology is used to elucidate regional thermal T – t histories by dating a variety of K-bearing minerals that record different parts of the geological evolution of a terrane. Many Ar–Ar applications in tectonics have been published. A novel application of Ar–Ar thermochronology was presented by Camacho et al. (2005), who used a variety of Ar–Ar techniques in combination with diffusion theory to determine the duration of a complete orogenic cycle (subduction and exhumation) in the Bergen Arcs of Norway.

Economic Geology

Ar–Ar dating is well suited for the timing of mineralization in ore deposits because K-bearing minerals are commonly associated either with the ore or with ore-forming processes. Minerals such as biotite, K-feldspar, muscovite, and alunite are commonly dated in such studies. Ar–Ar dating has been applied in the study of a variety of ore deposits including porphyry Cu–Mo (e.g., Quang et al. 2003), epithermal Au (e.g., Bissig et al. 2002), vein Au (e.g., Kontak et al. 1998; Mark et al. 2010), Mississippi Valley-type Pb (e.g., Sherlock et al. 2004), unconformity-type U (e.g., Polito et al. 2004), and diamondiferous kimberlitic (e.g., Phillips et al. 1999) deposits.

Detrital Provenance

Ar–Ar dating of single crystals of K-bearing minerals has provided useful insights into the provenance of sediments derived from adjacent source regions. Analogous to the U–Pb dating of single crystals of zircon, the dating of grains of detrital biotite and muscovite can be equally useful if the thermal history of the rocks has not been substantially disturbed. A recent overview of the use of Ar–Ar dating in detrital provenance studies is given in Hodges et al. (2005).

Paleomagnetism and the Geomagnetic Polarity Time Scale

Ar–Ar dating has been particularly useful in dating paleomagnetic poles for plate reconstructions as well as in refining the geomagnetic polarity time scale. An excellent summary is given in York (1984) with subsequent developments outlined in Spell and McDougall (1992).

Sedimentary Basin Evolution

Sedimentary basins have been the subject of intense study because of the opportunity to study a wealth of crustal processes as well as a rich source of ore and hydrocarbon deposits. Ar–Ar dating is generally considered to record higher-temperature processes in such basins and is also used in the study of the provenance of sediments. A recent overview of the use of Ar–Ar and other thermochronometers in understanding the thermal histories of sedimentary basins is given in Armstrong (2005).

Cosmochronology

One of the earliest applications of ^{40}Ar – ^{39}Ar dating was in the study of meteorites as well as lunar samples brought back from the US Apollo missions. In particular, there is a vast body of literature on the ^{40}Ar – ^{39}Ar dating of whole-rock basalts and related rocks which led not only to an increased understanding of the genesis of the moon and solar system but also to many refinements in the development of the technique. Many of these results are summarized in McDougall and Harrison (1999).

Advantages and Limitations

With a ^{40}K half-life of 1,250 Ma, the K–Ar and Ar–Ar methods are well-suited for dating most geological materials from the Paleocene to the age of the Earth and solar system. Dating very young materials, e.g., < 1 Ma, can be particularly challenging with the Ar–Ar method due to very short irradiation times and larger uncertainties resulting from variations in the neutron flux and proportionally larger corrections from blanks, neutron interferences, and mass discrimination in the mass spectrometer. However, extremely young rocks dating from historical times (i.e., the eruption of Mt. Vesuvius in 79AD) have been successfully dated using the Ar–Ar method (Renne et al. 1997; Lanphere et al. 2007).

In addition, the K–Ar and Ar–Ar dating methods occupy a unique position among all geochronological methods because Ar is a noble gas. As K–Ar and Ar–Ar ages are therefore particularly dependent on the temperature of geological systems, this has both its advantages and disadvantages. In particular, one of the greatest strengths is the ability to record the geological history of a sample over a range of temperatures. However, in the absence of additional geological and petrological information, it may not be possible to know if a K–Ar or Ar–Ar age represents a crystallization, metamorphic, or cooling age.

K–Ar

At present, there are two main advantages of the conventional K–Ar method. First, it is a method grounded on first principles, i.e., the method is completely independent of other geochronological methods. This is essential where reevaluation of fundamental physical parameters such as the K decay constant may be important (see section “[Radioactive Decay Scheme](#)”). Second, it is well suited for dating potassium-bearing fine-grained materials (such as clays or glauconites) where ^{39}Ar recoil would be problematic.

A major disadvantage of the K–Ar method is the sensitivity of a K–Ar age to the thermal history of the rocks. While a K–Ar age may reflect the formation age or crystallization age of rocks, this age can be readily disturbed or even reset due to a variety of geological processes such as slow cooling, thermal reheating, or regional metamorphism. For example, in many early studies, it was noted that K–Ar dates did not agree with either (a) dates for other potassium-bearing minerals from the same

rock or (b) ages using other geochronological methods (e.g., Rb–Sr, U–Pb). Thus, one of the most serious challenges with the conventional K–Ar method is that, in isolation, it is impossible to tell whether a K–Ar date reflects the time of crystallization, time of a subsequent metamorphism, or some time in between. There are some other disadvantages with conventional K–Ar dating. In the K–Ar method, absolute quantities of potassium and argon are measured on separate aliquots of the sample in order to calculate the ^{40}Ar – ^{40}K ratio and, hence, the age of the sample; consequently, K–Ar ages tend to have much larger uncertainties than Ar–Ar ages. Moreover, if the sample is inhomogeneous, this practice can significantly reduce the accuracy of the final age. In addition, because the sample is completely fused to measure K and Ar, only a single date can be obtained per analysis. Finally, relatively large quantities (milligrams) of pure sample are required for a K–Ar analysis which means that there must be significant quantities of sample available to be analyzed, also increasing sample preparation requirements.

Fortunately, all of these disadvantages are effectively eliminated by using the ^{40}Ar – ^{39}Ar technique.

Ar–Ar

There are numerous advantages in using the ^{40}Ar – ^{39}Ar method. It is more convenient in terms of analysis because only isotopes of Ar need to be measured from a single aliquot of sample, unlike K–Ar dating in which different techniques are required to measure K and Ar, respectively. Problems with sample inhomogeneity and differing machine calibrations are eliminated because all of the measurements are performed on the same sample with the same equipment. Because only ratios are needed (i.e., $^{40}\text{Ar}/^{39}\text{Ar}$), Ar–Ar ages will inherently be more precise than K–Ar ages and can typically achieve routine analytical uncertainties less than $\pm 0.5\%$. The high sensitivity of today's noble gas mass spectrometers means that very little sample is required for analysis; single-grain dating is routine. A variety of techniques (furnace/laser step-heating, total fusion, laser spot-fusion) can be employed to suit the goals of the project. The method can yield significant information on the thermal history of the sample. Finally, other argon isotopes can be used to infer some information about the chemical composition (K, Ca, Cl) of the sample.

Ar–Ar dating does have some disadvantages. A nuclear reactor with a suitable fast-neutron fluence is required. This also means that irradiated samples are radioactive and must be appropriately stored; safe handling and sample preparation procedures must also be developed. Neutron irradiation results in the formation of artificial Ar isotopes from K, Ca, and Cl which must be corrected in calculating an Ar–Ar age, leading to more complicated data processing. The irradiation also results in ^{39}Ar recoil, which can negatively affect the ages of very fine-grained samples or samples with μm -scale domains. Finally, all of these factors also mean that the method is generally more time consuming and costly in comparison to K–Ar dating.

Summary

The Ar–Ar method has largely superseded conventional K–Ar dating because of its numerous advantages. The presence of K-bearing minerals in a variety of rocks has led to the widespread application of Ar–Ar dating to solve a variety of geological problems involving the geological time scale, hominid evolution, structural geology and tectonics, economic geology, detrital provenance, paleomagnetism, the evolution of sedimentary basins, and the origin of extraterrestrial materials. Moreover, the strong relationship between argon mobility and temperature makes the Ar–Ar method an ideal thermochronometer. To apply it successfully, however, knowledge of the microstructural,

mineralogical, petrological, and geological context of the dated samples must be known in order to obtain meaningful interpretations of the age data. With this information, the real power of the Ar–Ar method lies in its unique ability to solve diverse problems in the earth sciences and to elucidate a significant portion of the temperature–time histories of geological terranes.

Laser spot dating; Single-crystal step-heating; Single-crystal total fusion

Definition

An analytical technique in Ar–Ar ($^{40}\text{Ar}/^{39}\text{Ar}$) dating in which a laser is used to heat single crystals of minerals in order to extract argon isotopes for measurement in a mass spectrometer.

Introduction and Modes of Operation

Improvements in the sensitivity of argon mass spectrometers have enabled the measurement of argon isotopes released from the single crystals of K-bearing minerals. In order to release the argon from the crystal structure, in an environment with minimal contamination from the atmosphere and experimental conditions, lasers have been employed in combination with low-volume extraction lines and sample chambers. The earliest use of lasers in single-crystal Ar–Ar dating was by Megrue (1967), who employed a pulsed ruby laser to analyze meteorite samples. York et al. (1981) documented the first use of a continuous-wave laser in a thermochronological study of metamorphic rocks and showed that such lasers could be used to progressively step-heat a single crystal to obtain an apparent age spectrum, analogous to that obtained by heating a much larger aliquot of crystals in a furnace. Further information about the step-heating technique and the interpretation of Ar–Ar age spectra can be found in the section “K–Ar and Ar–Ar Dating.” Since then, the use of single-crystal laser dating techniques in Ar–Ar dating has become widespread. Figure 1 shows a typical laser dating system and Fig. 2 shows a close-up of the sample chamber containing mineral grains to be analyzed.

Single-crystal $^{40}\text{Ar}/^{39}\text{Ar}$ laser dating can be performed in three modes: (1) step-heating, (2) total fusion, and (3) spot dating.

Laser Step-Heating

In laser step-heating, a large-diameter, defocused laser beam is used to progressively heat single crystals in a series of steps of increasing power (i.e., temperature) until the crystal has completely melted and fused into a glass bead. At each step, the argon isotopes released by the heating are analyzed in a mass spectrometer to obtain an $^{40}\text{Ar}/^{39}\text{Ar}$ age for that step. A defocused beam is essential in order to uniformly heat the entire crystal in each step. The complete sequence of steps

Fig. 1 $^{40}\text{Ar}/^{39}\text{Ar}$ laser system. The laser (in this case, a Lexel Ar-ion laser) sits horizontally on the bench. Mineral grains are placed inside the cylindrical steel sample chamber (see Fig. 2) on the *right-hand side* of the photograph on the stage of the binocular microscope. A CCD camera is aligned along the optical axis of the microscope and laser beam so that mineral grains can be viewed “live” on the television screen (at the *left*) as they are heated. The laser power is controlled by the rectangular console (foreground, *left*) and the sample chamber can be moved precisely in small increments in both the X and Y directions using the joystick controller (foreground, *center*)

(from low to high temperature) yields an $^{40}\text{Ar}/^{39}\text{Ar}$ apparent age spectrum. This technique can be

Fig. 2 Laser dating sample chamber. Single crystals of the samples to be analyzed are placed in small holes drilled into a metal (e.g., Al or Cu) planchet (*bottom, center*). The planchet is then placed inside a steel sample chamber with a viewport that is transparent to the laser beam radiation, and the chamber is evacuated under ultrahigh vacuum. In this system, the laser beam comes in horizontally from the *upper right* of the photo and is deflected downwards onto the mineral grains in the planchet by a circular mirror angled at 45° (*top, center*)

Fig. 3 Age contour or “chrontour” map of a single amphibole grain with an age gradient ranging from ~2,300 Ma in the grain core to ~2,700 Ma along the grain rim. Chrontours were constructed from 22 individual laser spot dates obtained within the grain (Modified after Lee et al. (1990))

used to elucidate potential age gradients within crystals from rocks which may have cooled slowly or been partially reset due to metamorphism or local reheating. One of the earliest geological applications is given by York et al. (1981). Lee et al. (1990) used both laser step-heating and laser spot dating (described below) to elucidate age profiles from rocks in a contact metamorphic zone. Laser step-heating is now one of the most common modes of single-grain laser dating. Typical types of lasers currently used for this mode of dating are continuous-wave lasers that emit in the infrared (IR) and visible wavelengths, such as CO₂ and Ar-ion lasers.

Laser Total Fusion

In single-crystal total fusions, a laser is used to completely fuse a single mineral crystal in one step using a focused or slightly defocused beam. The released argon isotopes are analyzed in a mass spectrometer to obtain an $^{40}\text{Ar}/^{39}\text{Ar}$ age for the crystal. This age is identical to the integrated age that would be obtained from an $^{40}\text{Ar}/^{39}\text{Ar}$ apparent age spectrum. Because this mode produces only a single age per crystal, it is most typically used in dating studies in which there may only be a limited amount of sample or in detrital or provenance studies of crystals which may have come from a variety of source rocks or regions which therefore reflect rocks of different ages. The data are commonly displayed in the form of a probability density diagram of total fusion age versus relative probability (i.e., frequency) (see K–Ar and Ar–Ar Dating). A thorough overview summarizing a variety of $^{40}\text{Ar}/^{39}\text{Ar}$ detrital studies is given by Hodges et al. (2005). Typical types of lasers currently used for this mode of dating are continuous-wave or pulsed lasers that emit in the infrared (IR), visible, and ultraviolet (UV) wavelengths, such as CO₂, Ar-ion, and Nd:YAG lasers.

Laser Spot Dating

In laser spot dating, a finely focused laser beam is used to ablate small volumes of sample *within* single crystals. The argon isotopes released by the ablation are analyzed to yield an age for that spot. Samples are usually prepared in the form of a single crystal with a flat surface perpendicular to

the laser beam (e.g., as a polished thick section) such that the laser can be used effectively as an age microprobe, in which laser spot traverses can be conducted from the core to the rim of a single crystal. Age contour (or “chrontour”) maps across an entire crystal can be constructed (Fig. 3) if a suitable number of sampling points can be obtained, e.g., Phillips and Onstott (1988), Lee et al. (1990), and Kramar et al. (2001). Typical laser beam diameters can produce spots as small as 5–10 μm in diameter, though typical applications employ larger (e.g., 20–50 μm) spots in order to reduce analytical uncertainties. This mode of dating is used to directly ascertain potential age gradients within crystals. A variant of this mode involves rastering the laser beam over a large area of the crystal (e.g., $100 \times 100 \mu\text{m}$) or drilling a line of spots in the form of a “trench” in order to obtain enough argon to measure in a single analysis with reasonable precision, e.g., Kelley and Wartho (2000). This variant is most commonly employed in Ar diffusion studies or in depth profiling. Typical types of lasers currently used for this mode of dating are pulsed lasers that emit in the IR and UV wavelengths, such as Nd:YAG, frequency-quadrupled Nd:YAG, and excimer lasers.

Advantages and Limitations

$^{40}\text{Ar}/^{39}\text{Ar}$ single-crystal laser dating has a number of advantages. Single-crystal analysis enables the unambiguous measurement of the distribution of Ar isotopes within a crystal, i.e., it eliminates the potential for the mixing of different Ar reservoirs from various sources which may exist in analyzing a mineral separate composed of tens or hundreds of mineral grains. In addition, the effects of contamination from other minerals or phases that may be present in larger aliquots of minerals can be reduced. Another advantage is that the amount of material that is required for analysis is significantly reduced, which may be particularly important in the analysis of trace or rare minerals. The reduced sample size also greatly simplifies and reduces the time required to prepare samples for analysis and also minimizes the volume of sample that must be artificially irradiated and safely stored.

This technique also has some limitations. The reduced sample size means that volumes of Ar derived from laser heating are proportionally smaller; this means that sufficiently old, K-rich, or large crystals should be dated to provide ages with acceptable precision. Alternatively, modified techniques such as rastering or trenching (discussed above) should be used. The smaller gas volumes generally mean that age uncertainties on single-crystal laser ages are somewhat larger than those derived from analyzing larger aliquots of sample. For laser step-heating, it is important that the laser radiation couples well with the mineral structure to ensure uniform heating of the crystal; for example, although Nd:YAG lasers have been successfully used to step-heat mafic minerals such as biotite and amphibole, they are known to have difficulty coupling with optically transparent minerals such as K-feldspar. Care must also be taken when performing laser spot dating analyses on single crystals which are inhomogeneous, e.g., those with exsolution lamellae or Ar reservoirs, as the resultant ages may reflect the ages of the different phases/reservoirs or a combined mixture of their ages.

Summary

Single-crystal laser dating techniques are now commonly employed in Ar–Ar dating studies. Depending on the type of application, either pulsed lasers or continuous-wave lasers may be used. Continuous-wave lasers are typically used for single-crystal step-heating and total fusions;

in this case, the laser beam radiation must couple well with the mineral structures to be heated (i.e., laser energy needs to be efficiently absorbed by the mineral), and CO₂ lasers are most commonly used in current applications because the wavelength of the radiation appears to couple efficiently with all oxygen-bearing compounds. Pulsed lasers are typically used for laser spot dating; UV wavelengths are commonly employed because of the improved efficiency in ablating a large variety of silicate minerals. Numerous advantages of single-crystal dating have led to its widespread application in a variety of Ar–Ar dating studies.

Alpine Terranes (K-Ar/Ar-Ar)

Jan R. Wijbrans*

Earth Sciences, Deep Earth, Faculty of Earth and Life Sciences, VU University, Amsterdam, The Netherlands

Synonyms

Tertiary metamorphic terranes; Young metamorphic terranes

Definition

Alpine terranes in the strictest sense can be defined geographically as terranes belonging to the region in south–central Europe from the Maritime Alps and Ligurian Alps along the Mediterranean coast between Genova and Marseille in the west and the Vienna basin in the east where the Tauern window ends in the northern belt and the Julian Alps of Slovenia in the southern belt.

In a geological sense, much of southern Europe from the Betics in southern Spain and the Rif in northern Morocco to the Hellenides in Greece much of southern Europe forms part of the Alpine orogeny. In fact, when viewed as resulting from the collision of the Arabian–African continent in the south and Eurasia in the north, the Alpine orogeny can be traced much further to the southeast to include Turkey and metamorphic complexes along the Persian Gulf to end in Oman in the far southeast (Fig. 1).

The term Alpine terranes is sometimes used to include young Tertiary mountain belts worldwide.

When approached from the perspective of metamorphic processes, the Alpine terranes include the crystalline cores of orogens formed by metamorphic processes since the Cretaceous. Alpine terranes thus form a subset of the metamorphic terranes.

Introduction

For the purpose of the present summary, it is useful to propose a mixed definition based mainly on timing of metamorphic processes but including geographical considerations. Alpine metamorphic terranes contain the evidence for processes that deformed the mid- to deep levels of the continental crust during the collision between Eurasia and Arabia–Africa since the Cretaceous (Fig. 1). Although tectonic processes developed broadly synchronously, it is appropriate to exclude the Himalayan orogeny here because it resulted from the collision of India with Eurasia, and on closer inspection, the tectonics and the time lines of orogenic processes are quite different. In its broadest sense, the term “Alpine terrane” is used by some as a generic term for all Tertiary metamorphic belts worldwide. Here we will follow the more common definition: the mountain belts situated in south–central Europe extending in the southeast as far as the Persian Gulf, with an occasional aside to processes occurring in insights developed for mountain belts elsewhere.

Much of the central and southern Eurasian continental crust shows evidence for severe alteration during the Variscan orogeny, roughly spanning the time period of ca. 380–300 Ma. In the southern

Fig. 1 The Alpine fold belt in southern Europe and the Middle East (Published with permission of the author, H.W. Goede)

Arabian–African continent, the crystalline basement consists of rocks of ca. 500–700 Ma, which belong to the Pan-African event in the east, and Maghrebien rocks of Variscan age in the west. The Rif mountains in northern Morocco form the southern extent of an Alpine orogenic arc bordering the Alboran Sea.

Between the main northern and southern blocks, during the Mesozoic, there were smaller blocks of continental crust that were exposed to an extensional regime in Triassic and Jurassic times (e.g., Manatschal 2004). Extension at that time was accompanied by mafic underplating and severe alteration of the continental lower and middle crust between ca. 280–200 Ma. Evidence for this period of pre-Alpine evolution in this domain can be found in the Austro–Alpine thrust sheets in Eastern Switzerland and Austria, in the bordering regions of northern Italy, in the Pyrenees, and in the Catalan coast ranges. Rocks of this age in the Southern Alps, south of the Insubric line separating the Internal Alps in the north from the Southern Alps, are interpreted as forming the thinned margin of the Adria micro-continent (Bertotti et al. 1999). In conclusion, although in quite a substantial part of the Alpine orogen metamorphic rocks of Triassic and Jurassic age are exposed, tectonic analysis suggests strongly that these rocks were formed during a phase of rifting that preceded the phase of continental collision that formed the Alps.

The collisional phase that initiated the Alpine orogeny was accompanied by deep subduction of the continental crust, and much current research is focused on finding out when these phases of deep subduction occurred. In much of the Alpine domain, Paleocene–Eocene ages are found. In the west, in the Betic Cordillera, subduction-related metamorphism is possibly as young as the Oligocene, but in parts of eastern Europe, in the Eastern Alps, in the Julian Alps of Slovenia, and in the internal Hellenides around the Ossa and Olympos ranges, Cretaceous ages of 90–100 Ma are associated with the blueschist- and eclogite-forming events.

In several sectors of Alpine Europe, the phase of deep subduction was followed by a phase of medium- to high-temperature metamorphism at mid-crustal depths during the Miocene; examples can be found in the Betics, the Lepontine domain of the Swiss Alps, the Tauern window in Austria, and the Greek Cyclades. Granitoid magmatism and associated volcanics are found in the peri-

Adriatic domain of the southern Alps in northeast Italy, with ages of ca. 45 Ma for the Adamello (Schoene et al. 2013), 32–24 Ma for the Bergell (Blanckenburg 1992), and ca. 21 Ma for the Pohorje granites of Slovenia (Fodor et al. 2008). In the Greek Cyclades, granites intruded during the Miocene (Altherr and Siebel 2002).

Active volcanism related to subduction can be found in the Alboran domain in the west, in the Calabrian arc north of Sicily, and in the Hellenic arc, where Santorini is the most prominent volcano. Late Miocene to recent potassic and ultrapotassic volcanism is found in the Betics in southern Spain and in the Roman province in central Italy.

Historical Perspectives

While the early efforts of dating the crystalline rocks of the Alps proved quite effective in outlining the broad age groups for the rocks found in the Alps, the general complexity of the Alps as an orogen, and the fact that initially quite large samples needed to be used for isotopic analysis, prevented the early workers from obtaining a true picture of the Alpine geochronology. However, new insights from mineralogy and petrology on the one hand, and tectonics on the other, helped in refining the image that we have of Alpine processes. The early division in Eo-Alpine, Meso-Alpine, and Neo-Alpine periods for rocks yielding Mesozoic, Paleogene, and Neogene ages has largely been abandoned in the light of a better understanding of Alpine tectonics.

Probably the most important result of the early efforts of understanding Alpine geochronology was the observation that minerals when dated with the K/Ar method yielded systematically younger ages when compared with their Rb/Sr ages (e.g., Jäger 1979). This observation, combined with the subsequent realization that minerals that were formed during the ca. 320–350 Ma Variscan yielded Alpine ages in a section with increasing overprinting temperatures during the Alpine orogeny, led to the understanding that the isotope systems in minerals such as muscovite and biotite displayed open- or closed-system behavior with respect to the radiogenic isotopes formed from radioactive decay in these minerals. The Berne geochronology group was in an ideal situation to make this observation because Swiss petrologists using the results from experimental petrology had come quite far with assigning temperature estimates to the prograde temperature sequence in the Swiss Alps from the external units in the north and northwest to the internal zones in the south (e.g., Frey et al. 1974). As a result of this early work, the transition from closed to open system in the K/Ar and Rb/Sr systems of common rock forming minerals such as muscovite and biotite could be assigned a quantitatively determined temperature, for which the Berne group used the term “blocking temperature” (Jäger 1979). As the blocking temperatures of minerals appeared to be intrinsic properties, different temperatures could be assigned to the age of minerals; it became possible to determine quantitative cooling rates for rocks cooling after metamorphism.

At the time that the Berne team was quite far advanced with calibrating the temperatures for the transition of closed- to open-system behavior by comparison with temperature estimates from thermobarometry, other researchers focused on experimental determination of diffusion rates for radiogenic isotopes such as isotopes of Sr and Ar in minerals (e.g., Mussett 1969; Giletti 1974a; b). The mathematical equations describing diffusion in objects with simple shapes such as a sphere or a cylinder can be derived under the assumption that diffusion of particles and heat obey the same physical laws and hence can be described using similar mathematical equations. The diffusion equation allows calculation of loss of, for example, radiogenic daughter isotopes from minerals with time at a range of temperatures but can also be used with some success to describe the diffusion of cations necessary to build new minerals as metamorphic reactions proceed. As an example, time

spans required to achieve a threshold value of 90 % loss of radiogenic daughter isotope are very long at low temperatures and become gradually shorter at higher temperatures, and full resetting can be expected when the time for 90 % loss of radiogenic daughter isotopes is in the same order of magnitude as the time span of the metamorphic overprinting. The diffusion equation also predicts a grain size effect, with larger grains taking longer to lose all radiogenic daughter isotopes. Finally, the mathematics of diffusion requires that once the diffusing isotope has diffused out of the crystal, it is effectively taken away and will not increase the concentration of isotopes at the surface of the crystal occupying the intergranular pore space. Some of the complexities in the interpretation of age results in young mountain belts can be attributed to the fact that not all of these boundary conditions are always fulfilled. In the next section examples will be given of such complexities in the interpretation of age data in young mountain belts.

Complexities in Interpretation

In Alpine metamorphic terranes, isotope geochronology can be particularly powerful because in this age range (generally processes take place during the period younger than 66 Ma) the resolving power of the isotopic dating techniques is high, and it can be expected that different phases of metamorphic overprinting can be resolved. In areas that have experienced high temperatures and where recrystallization has gone to completion, results of isotopic dating can be interpreted as recording cooling, and the ages that are thus obtained are recording closure temperatures (see chapter ► [Metamorphic Terranes](#)). Dodson (1973) defined the closure temperature in a cooling system as the temperature of the system at the time defined by its measured isotopic age. Using the mathematics of diffusion, Dodson demonstrated that a closure temperature can be calculated when an activation energy, E_a , and diffusion constant, D_0 , for a mineral phase are known. A closure temperature is defined for mineral phases that initially do not contain any radiogenic daughter isotope, and the actual value depends on the radius of diffusion and rate of cooling of the rock. In an ideal crystal, the radius of diffusion is likely to be equal to the grain radius, but in deformed or twinned crystals, the diffusion radius is more likely to be the radius of the subgrains formed during twinning or deformation and can be substantially less than the original grain radius. Further, while based on the mathematical equations for diffusion, Dodson's closure temperatures are implicitly defined only for the situation where the concentration of radiogenic daughter isotope at the grain boundary is zero. In reality, finite concentrations of radiogenic daughter may occur especially in cases where the mobility in the intergranular space is decreased. Examples of the simple case of rocks cooling from high temperatures (>ca. 600 °C) can be found in every Alpine metamorphic terrane that reached high temperatures during metamorphic overprinting. Examples of cases where the boundary conditions for Dodson's closure temperature definition are violated can be found in most mountain belts in the regions where metamorphic temperatures were lower (<ca. 500 °C), when minerals formed at a temperature below their closure temperature, or where minerals were not fully reset and still contain radiogenic daughter isotope from the period preceding the studied metamorphic event. The boundary conditions for calculating a closure temperature may also be violated during high-pressure and ultrahigh-pressure metamorphism when rock porosity is severely decreased, thus effectively preventing transportation of radiogenic daughter isotope out of the system once the first step of diffusion out of the crystal lattice has occurred.

Examples

In a study of the metamorphic evolution of the Mulhacen complex in the Betic Cordillera in southern Spain by De Jong et al. (1992), muscovites yielded uniform ages in the range of 11–12 Ma, whereas observation of the structures in the rocks suggested a fairly complex tectonic evolution. The uniformity in K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ ages suggested that much of this tectonic complexity predated the high-temperature event. In order to shed additional light on this history that could not be measured from analysis of normal matrix muscovite, a megacryst of ca. 5 mm diameter, i.e., some 20 times the size of the matrix, was measured using a spot heating laser technique. Relying on the prediction of diffusion theory that diffusion loss is in part controlled by the grain radius, it was expected that a signal predating the pervasive 11–12 Ma event could be found. From spot analysis using an argon ion laser, a concentric pattern of ages increasing towards the center of the grain was found, indicating that the megacryst was at least 27 Ma old. This can be taken as confirmation that grain size and diffusion radius define isotopic closure: the smaller grains record the younger cooling age, whereas a larger grain yielded a much older cooling age.

An important observation was made by Baxter et al. (2002), who worked in high-temperature metamorphic rocks in the Simplon area, part of the internal zone of the Swiss Alps. Here, it appeared that there was a systematic bias in $^{40}\text{Ar}/^{39}\text{Ar}$ ages of biotites that were measured from mica schists and biotites in meta-basalts. As the rocks were interlayered in a relatively small area, it could be safely assumed that their metamorphic histories were the same. Also the grain sizes were in the same range. Yet the ages obtained from the minerals from the meta-basalt were systematically higher than those found from the mica schists. The interpretation was that the diffusivity of radiogenic daughter isotope was less in the meta-basalt and higher in the mica schist. A lower diffusivity in the intercrystalline pore space may imply that a substantial concentration of radiogenic daughter isotope could be maintained in the pore space during the peak temperatures of metamorphic overprinting. Isotopic closure is firmly based on diffusion theory that assumes that the concentration of radiogenic isotope in the pore space remains zero at all times, i.e., when radiogenic daughter isotope is removed from the crystal by volume diffusion, it is also removed from the system. When due to lower diffusivity a higher concentration of radiogenic daughter isotope can be maintained, this would result in the preservation of systematically higher isotopic ages.

At metamorphic temperatures that are lower (i.e., < ca. 600 °C) and at metamorphic pressures that are higher, the complexity of the preserved isotope signal is expected to increase; at lower metamorphic temperatures, isotopic resetting may not go to completion as at these temperatures the system remains below the closure temperatures of various minerals (Warren et al. 2012). At increased burial depth, the porosity of the rock will decrease, and with the concomitant decrease in diffusivity, the concentration of radiogenic isotopes at the grain boundaries will increase. As a result of these elevated concentrations of radiogenic isotopes, full resetting of geochronometers may not be achieved.

As a result accumulation of radiogenic daughter isotope may start at different times in different crystals of the same mineral phase. Complex crystallization histories potentially can be resolved, with a combination of detailed microstructural characterization and access to single crystal or spot dating techniques as demonstrated by Beltrando et al. (2008). Another level of complexity is added in the situation where a preexisting mineral assemblage is overprinted. In an early study of this situation, Wijbrans and McDougall (1986) demonstrated that phengites formed during early high-pressure metamorphism at or before ca. 45–50 Ma in Naxos, Greece, were progressively overprinted by younger more muscovitic phengites and true muscovites during a younger metamorphic phase that ranged in peak temperature from >450 °C to ca. 700 °C in the period 15–11 Ma. It could be

demonstrated in this case that as long as early phase phengites remained present in the rock, an elevated age signal was found. This observation underlined the conclusion that recrystallization is the faster, more effective mechanism to reset the isotope system. In addition, it was argued that given the observation that full resetting of the early phengites was not observed, it should follow from diffusion theory that the duration of the subsequent thermal pulse that caused the high-temperature mineral assemblages may have been rather short.

In a study of the blueschist – greenschist metamorphism of the internal Hellenides, Lips et al. (1998) by careful selection could isolate and date various phases of blueschist phengites and younger greenschist muscovites in an age range between 90 and 40 Ma, including an example of a Variscan orthogneiss that exhibited ca. 320 Ma protolith muscovites. They also found overprinting of Alpines phengites with ages of ca. 65 Ma. At no time since the Cretaceous were metamorphic temperatures high enough to fully reset the isotope systems of the white micas; complete ranges in ages from Variscan protolith ages to late stage Alpine greenschist facies ages were preserved.

In the internal Western Alps during Alpine collision, high- and locally ultrahigh-pressure metamorphic conditions were reached during the Paleocene–Eocene, as confirmed by U/Pb zircon dating, Sm/Nd dating, and Lu/Hf dating of garnet-bearing mineral assemblages (Rubatto and Hermann (2003), Lapen et al. (2003)). The K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ records of phengites and muscovites in these areas yielded a complex picture with ages in the range of ~40 Ma to 120–200 Ma, with outliers as high as ~300 Ma (e.g., Scaillet 2002). The simplest interpretation would be to accept the ca. 40 Ma ages as consistent with the U/Pb and Sm/Nd and Lu/Hf data, and everything older is an artifact caused by excess argon. However, the protolith age of the orthogneiss Variscan granite with ages up to the range of ca. 300 Ma would be consistent with a Variscan protolith history and might suggest inheritance of an older argon signal that is preserved despite Alpine tectonism and metamorphism in the Eocene.

Much of the complexity in the interpretation of K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ age data is caused by the mobility of ^{40}Ar in natural rock systems. Formed by the decay of ^{40}K , ^{40}Ar is a noble gas. As a neutral atom, argon is not a constituent part of a crystal lattice of the mineral in which it formed. The mobility of argon in minerals is best described by a volume diffusion mechanism, for which a pre-exponential diffusion constant D_0 and activation energy E_a can be determined experimentally. Although volume diffusion in pristine, undeformed crystals is likely to be a very slow process, diffusion in a compact aggregate of minerals along defects and grain boundaries is considered to be a faster process as the permeability along the grain boundaries is higher than within the crystal itself (Lee 1995). Porosity may vary from very low to high, as pore space may range from very low volume without any interconnection to full interconnection allowing advection of a fluid through the rock. In order to release the radiogenic argon trapped within the crystals, the slowest mechanism is via volume diffusion, whereas other processes such as grain boundary diffusion and recrystallization are likely to be much faster, as the bonds between the ions forming the crystal lattice are broken in the latter process, and trapped argon can be released via grain boundaries (Wijbrans and McDougall 1986).

The interpretation of dating results from rocks from Alpine terranes thus may be complicated by the degree of mobility of argon during metamorphic overprinting. When ages are found with K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating that are older than expected, the system contains extraneous argon. For practical purposes, two common forms of extraneous argon can be defined: excess argon that is released into the system when potassium-bearing minerals break down and inherited argon, which is radiogenic Ar that was incorporated in the lattice of a preexisting mineral. In the case of inherited argon, traces of a prehistory may not have been fully erased during overprinting and can be used in favorable cases to further constrain the thermal evolution of the rock.

Summary and Conclusion

In the Alpine orogenic belt in central and southern Europe, rocks were exposed to elevated temperatures and pressures caused by tectonic processes of subduction and collision of continental crustal blocks during closure of oceanic basin such as the Tethys and Paratethys basins. These processes occurred predominantly during the Paleogene and Neogene and in some sectors as early as the Late Cretaceous. Earlier processes recorded in the rocks appear to be related to the processes predating the Alpine subduction and collision orogen. Evidence for earlier processes and artifacts caused by the mobility or in cases the lack of mobility of radiogenic daughter isotopes add to the complexity of interpreting isotopic age data in the low-temperature and high-pressure domains in mountain belts.

Because metamorphic processes in the Alps occurred during a relatively young period of Earth's history, much of the tectonic evolution causing metamorphism can be resolved in time. As a result many of the mechanisms of behavior of isotope systems were first described in the Alps.

Metamorphic Terranes ($K\text{-Ar}/^{40}\text{Ar}/^{39}\text{Ar}$)

Jan R. Wijbrans*

Department of Earth Sciences, Faculty of earth and Life Sciences, VU University, Amsterdam, The Netherlands

Synonyms

[Metamorphic basement](#); [Metamorphic belts](#)

Definition

Metamorphism in its widest sense refers to processes of alteration of rocks within the Earth crust and mantle that cause recrystallization of an original mineralogy to form new minerals that are thermodynamically stable at depth and thus reflect in their chemistry and mineralogy the changed physical conditions of pressure, temperature, stress regime, and partial pressures of volatile phases such as H_2O , CO_2 , CH_4 , and others during the time of recrystallization.

Metamorphism covers a spectrum from partial recrystallization to complete recrystallization. Partial recrystallization may reflect processes within a single cycle (pluri-facial metamorphism) or multiple cycles of metamorphism spaced out in time (poly-metamorphism). Retrograde metamorphism reflects often partial recrystallization after peak metamorphism.

Terranes are units of rocks at the crustal scale that share common geological features and a common geological history.

Metamorphic terranes therefore are terranes that consist largely of metamorphic rocks that share a common history of burial, metamorphism, and exhumation.

Introduction

Much of the continental middle and lower crust consists of metamorphic rocks. Much of the upper mantle, as far as we can tell from mantle rocks exposed at the Earth surface in ophiolite units and from xenoliths brought up from the upper mantle by magma transport, is also metamorphosed. In the oldest nuclei of continental crust, preserved Archean cratons, metamorphism may range from very low grade in the greenstone belts to granulite grade in the basement gneiss terranes. From the early Proterozoic onward, metamorphic terranes are often found in long and narrow belts, reflecting the fact they formed along the margins of plates of continental crust or by continent—continent collision processes (Fig. 1).

The general objective of geochronological analysis of metamorphic terranes is to shed light on the age of the protoliths and to place time constraints on the prograde (burial) path, peak metamorphic temperature (T) and pressure (P) conditions, and cooling after the peak of the metamorphic event, often during exhumation of the rocks (Fig. 2). Metamorphism is the alteration

of the mineral content of rocks caused by either changing PT conditions during burial caused by subduction or continental collision and associated rock deformation events or by heat or fluid advection as is, for example, the case when granites intrude into higher crustal levels or when basaltic magma underplates the continental crust.

Peak temperatures reached during metamorphism may range widely from ca. 400°C for the prehnite–pumpellyite facies to temperatures in excess of 900–1,000°C for the ultrahigh-temperature domain of the granulite facies. Metamorphic pressures recorded in crustal rocks in extreme cases are known to have exceeded lithostatic pressures consistent with what can be expected for normal crustal thicknesses by at least three times, suggesting either that during subduction or collision events, crustal rocks may have been pushed to great depths or that tectonic stress may build up to values substantially exceeding the normal lithostatic pressure. Minerals diagnostic for ultrahigh pressure include coesite and diamond that form at pressures in excess of 2.5 and 3 GPa, respectively.

For slowly cooling metamorphic terranes, the K-Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ geochronological techniques record ages usually interpreted as corresponding to the Ar closure temperatures (Dodson 1973) of their constituent minerals. Although closure temperature is dependent on the grain size of the minerals, such ages typically reflect the time at which the rocks cooled below ca. 500–550°C for metamorphic hornblende, ca. 150–400°C for K-feldspars, 360–420°C for metamorphic muscovite, and 280–330°C for metamorphic biotite, respectively. The exact “closure” temperatures for which timing information is obtained may be more difficult to determine, as they depend on cooling rate and radii of the crystal domains over which diffusion occurs. The determination of the exact closure temperature may be hindered by partial recrystallization or deformation, as under such conditions non-volume diffusion processes may have altered the age of the mineral.

As a consequence, the K-Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ techniques can typically be used to measure the age of metamorphic peak temperatures in those areas where the peak temperature has not exceeded

Fig. 2 Section through a convergent margin and PT diagram showing the PT fields of the various metamorphic grades. *I*, prograde path; *II*, peak metamorphic pressure; *III*, peak metamorphic temperature; *IV*, retrograde path

temperatures of 400–550°C for considerable amounts of time, i.e., at the prehnite–pumpellyite, greenschist, blueschist, and lower amphibolite facies metamorphic grades (Warren et al. 2012).

In higher-grade metamorphic terranes, the K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ methods are useful to constrain the cooling path of the rocks to temperatures below the closure temperatures of hornblendes, muscovites, biotites, and K-feldspars, respectively. The K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ methods can be applied to a wide range of K-bearing minerals and rocks, although hornblendes, micas, and K-feldspar are the most widely used minerals used for dating in metamorphic terranes.

Historical Perspectives

The K–Ar method has been in use since the 1950s, whereas the $^{40}\text{Ar}/^{39}\text{Ar}$ method was first developed in the mid-1960s and has since become the preferred method for dating by the ^{40}K – ^{40}Ar isotopic system. Whereas the K–Ar technique was quite successful in dating of volcanic and simple igneous rocks, it became apparent that the method did not always work well in old,

Table 1 Closure temperature ranges

Mineral	Temperature range (°C)
K-Feldspar	~150–400
Biotite	~280–330
Muscovite	~360–420
Hornblende	~500–550

Modified from Johnson and Harley (2012)

complex Precambrian metamorphic basement rocks, where consistently younger ages were often found in rocks that had demonstrably complex extended tectonic histories (e.g., Kinny et al. 1990). Moreover, researchers working in younger, Alpine metamorphic rocks found that in rocks and minerals dated with both the Rb/Sr dating technique and the K–Ar dating technique, the K–Ar technique often yielded systematically younger ages (e.g., Armstrong et al. 1966). This observation was used with advantage, when combined with estimates for metamorphic temperature deduced from the rocks used for dating, to estimate an empirical temperature reflecting the opening and closing of the isotopic system, a so-called “blocking” temperature. The blocking temperature for a mineral was defined as the temperature at which the isotopic system was reset during metamorphic overprinting, yielding for the first time temperatures above which isotopic ages could not be preserved (Jäger 1979). Clearly, under such extreme conditions, the K–Ar technique may only yield a partial answer to the question of timing of the tectonic evolution of the crust.

During this same period, the $^{40}\text{Ar}/^{39}\text{Ar}$ step-heating method was used to derive diffusion parameters for the diffusion of argon through the crystal lattices of various K-bearing minerals. Results of these first attempts to measure diffusion rates in hydrous minerals such as biotite and hornblende were unreliable as the mineral structures become instable due to dehydration reactions in vacuo (Mussett 1969; Hoffmann 1979). When such minerals were kept stable at high temperatures under hydrothermally controlled pressures, the diffusion results were more predictable (e.g., phlogopite, Giletti 1974; hornblende, Harrison 1981). The experimentally determined diffusion parameters, i.e., the pre-exponential coefficient, D_0 , and activation energy, E_a , could thus be used to predict diffusion loss from the crystal lattice of minerals at elevated temperatures. This approach led to the definition of a closure temperature (Dodson 1973), formally defined in a system cooling from high temperature as the temperature of the mineral at the time determined by its isotopic age. In contrast, a blocking temperature refers to an empirically calibrated temperature of resetting of isotopic ages in minerals. Although very powerful for the description of cooling systems, the use of closure temperatures to describe the loss of isotopic daughters during reheating is more complex, because in practice when the original mineral remains stable, the duration of the overprinting pulse, grain size, and degree of deformation play a role in affecting the age of the rock or mineral. Several researchers have attempted to model diffusion numerically using modified heat flow codes (Lister and Baldwin 1996; Wheeler 1996); this approach is particularly useful to test the effects of various parameters that may influence resetting by diffusion.

Diffusion is typically a rate-limiting process, so to be measured accurately a diffusion experiment needs to be carried out within the mineral’s stability field. Because the amounts of diffusion loss during experiments are very low, diffusion experiments present many analytical challenges; the results of several carefully controlled experiments are given in Table 1. An important consideration is that Ar diffusion may result from different mechanisms that occur simultaneously in minerals. In a perfect crystal lattice, diffusion of argon will proceed by a point defect process (also commonly known as volume diffusion); the large argon molecule has to push lattice ions out of the way in order to migrate through the lattice. Because the neutral argon molecule cannot substitute

for the lattice-forming ions, an exchange mechanism for Ar diffusion is not likely to occur. However, deformed crystals will contain defects or dislocations of the crystal lattice. Such defects will also diffuse through a crystal lattice at elevated temperature. Dislocation-driven diffusion and the point defect diffusion process are likely to have different diffusion constants and activation energies (Lee 1995) and thus may lead to varying estimates for closure temperatures. These considerations have led some researchers to suggest that true volume diffusion is so slow that it is not an effective means of mass transport, even at geological timescales at temperatures commonly occurring during metamorphism (Villa 1998).

Under the assumption that anhydrous minerals such as K-feldspar do not undergo phase changes during laboratory heating in vacuum, and hence argon loss during stepwise heating will follow a volume diffusion-governed process, it was argued that it is possible to model complex patterns of apparent age spectra assuming a finite number of sub-crystal sizes with different radii for diffusion (Lovera et al. 1989). Such a model could then be used to imply a discrete cooling history at geologically relevant time scales. Another approach, using higher-temperature geochronometers and lower-temperature geochronometers based on other isotopic decay systems such as U/Pb, Sm/Nd, and Rb/Sr, has been very useful in the quantification of crustal evolution studies (Kalt et al. 2000).

General Description

The $^{40}\text{Ar}/^{39}\text{Ar}$ method can be applied successfully in metamorphic terranes provided that the temperature history is well known from thermobarometric studies, thus linking the measured ages to the PT history of the rock. In this section, some examples of different time slices of Earth history will be discussed.

The oldest rocks on Earth dated successfully with the $^{40}\text{Ar}/^{39}\text{Ar}$ method are from the Kaapvaal and Pilbara cratons, both now situated in the southern hemisphere. In the Kaapvaal craton, komatiites from the Onverwacht Group in Barberton were dated at 3.45 Ga by Martinez et al. (1984), and the ages were interpreted to record the timing of lower-greenschist facies overprinting of the volcanics shortly after deposition. Layer et al. (1998) obtained an age of 3.18 Ga on the Nelshoogte pluton. In the Pilbara craton of Western Australia, Wijbrans and McDougall (1987) published hornblende ages as old as 3.2 Ga from the Western Shaw greenstone belt and demonstrated that within the adjacent granitoid domes, amphibolite facies metamorphism continued until 2.95 Ga. Subsequent work (Davids et al. 1997; Zegers et al. 1999) showed that in the Pilbara craton, also 3.4 Ga rocks have been preserved in the greenstone belts.

The metamorphic evolution of several Proterozoic metamorphic terranes has been studied using the $^{40}\text{Ar}/^{39}\text{Ar}$ method. Studies have focused on the metamorphic evolution of the early Proterozoic Arunta block in Australia and the eastern part of the Baltic shield in Scandinavia. Early Proterozoic mobile belts are relatively narrow metamorphic terranes in the Archean cratons, for example, the Limpopo belt in Southern Africa, the Capricorn belt in Western Australia, and the Nagsugtoqidian belt in Greenland are examples of such terranes that experienced metamorphic overprinting in the period ca. 2,000–1,700 Ma. The younger Grenville metamorphic event is most pronounced in North America characterized by ages in the range 1,200–800 Ma. Grenville-aged rocks are widespread and have been found in the Baltic Shield and in South America, where they can be straightforwardly linked to the core Grenville of North America; Grenville-age rocks also occur in Asia.

Younger Proterozoic metamorphic terranes can be found in the southern continents that formed part of Gondwana at a later stage of their history. For example, Pan-African metamorphic belts occur as relatively narrow mobile belts of ca. 500–600 Ma in age, and Pan-African age mobile belts occur, for example, in Northeast Africa, Egypt and the Sinai, Southeast Africa, Madagascar, India, and Western Australia.

Early Paleozoic metamorphic terranes occur in the Atlantic domain, in the Caledonian belt of western Scandinavia, eastern Greenland, and Eastern North America. HP and UHP rocks of the same age occur in the Urals and the Central metamorphic belt of China, whereas in southeastern Australia the Ordovician Lachlan fold belt is a low-grade slate belt.

Very young metamorphic terranes have been described tectonic systems that are active at present, such as the case of ongoing continental collision in, e.g., the Karakorum (Zeitler 1985), South Island, NZ (Chamberlain et al. 1995), and the D'Entrecasteaux Islands off the coast of Papua New Guinea (Baldwin et al. 2004), where Pliocene UHP rocks are exposed.

Summary and Conclusion

Much of the continental crust exposed within the continental interiors consists of metamorphosed rocks. These rocks can be conveniently grouped in terms of the age of metamorphism as recorded by common $^{40}\text{Ar}/^{39}\text{Ar}$ geochronometers such as K-feldspar, biotite, muscovite, and hornblende. Such a division illustrates the evolution of the continental crust through time from the early Archean exposed in the continental interiors to the youngest metamorphic rocks found in the rapidly exhumed rocks at the continental margins. Metamorphic rocks are important in that they often constitute the only record of evolution of the continental crust and bear evidence for tectonic processes in the geological past.

Lu-Hf Dating: The Lu-Hf Isotope System

Jeff Vervoort*

School of the Environment, Washington State University, Pullman, WA, USA

Definition

The radiogenic isotope applications of the Lu-Hf system utilize variations in ^{176}Hf resulting from the radioactive decay of ^{176}Lu to ^{176}Hf and variations in the Lu/Hf ratios in rocks and minerals. It is used both in geochronology, primarily in rocks containing a high Lu/Hf phase, and in tracer isotopic applications, to track the chemical evolution of the Earth and other solar system materials and to constrain the sources of magmas and sediments.

Introduction

The Lu-Hf isotope system, with applications to geo- and cosmochemistry, was first investigated in the early 1980s (Patchett 1983b; Patchett and Tatsumoto 1980a, b, c, 1981) following the successful implementation of the Rb-Sr and Sm-Nd isotope systems several years earlier.

There are some obvious similarities between the Lu-Hf and Sm-Nd isotope systems and, as a result, they have long been used in concert in a wide range of studies (e.g., Beard and Johnson 1993; Blichert-Toft and Albarède 1997; Johnson and Beard 1993; Patchett and Chauvel 1984; Patchett 1983b; Salters and Hart 1991; Vervoort and Blichert-Toft 1999; Vervoort et al. 1999). In these two systems all elements are lithophile and refractory with high condensation temperatures. Because of these characteristics it has long been assumed that their abundances in the Earth can be approximated by chondritic meteorites (see discussion below). In addition, all elements in these systems behave incompatibly during melting and are concentrated in the melt over the residual solid. In both systems, the daughter element (e.g., Nd, Hf) is more incompatible than the parent, leading to lower Sm/Nd and Lu/Hf ratios in the melt than the residual solid. As a result, the $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{176}\text{Hf}/^{177}\text{Hf}$ ratios in magmatic rocks are highly correlated (e.g., Chauvel et al. 2008; Johnson and Beard 1993; Patchett 1983a; Salters and Hart 1991; Vervoort and Blichert-Toft 1999). Both Lu and Hf are highly immobile and insoluble and, as is the case with the Sm-Nd system, are thought to be resistant to perturbations and retain their isotopic information through significant degrees of alteration and metamorphism.

In the case of the Lu-Hf isotope system, the parent is the heaviest of the rare-earth elements (REEs) and has broad geochemical similarities with all other +3 valence REEs. The daughter element, however, is not an REE, but a high-field-strength element (HFSE) with a +4 valence and, as such, can behave much differently than the REEs. These differences can confer some advantages to the Lu-Hf isotope system for both geochronology and tracer isotopic work as will be discussed below.

Although the Lu/Hf ratio is fractionated during magmatic processes, the degree of this fractionation, as is the case for Sm-Nd, is not very large. This results in small variations in Lu/Hf ratios between not only rocks within a comagmatic suite but also for most mineral phases within individual

*Email: vervoort@wsu.edu

rocks. This lack of parent/daughter variation severely limits the application of the Lu-Hf chronometer, much as it does for the Sm-Nd isotope system. Therefore, whole-rock Lu/Hf isochrons of truly comagmatic suites of rocks either have too limited variation in Lu/Hf ratios to provide precise ages or, if there is a significant Lu/Hf variation, chances are the suite of rocks used in creating the isochron was not truly comagmatic. There are a few phases, however, with high affinity for Lu, which make them highly useful in geochronology in both magmatic (e.g., apatite) and metamorphic (e.g., garnet, lawsonite) rocks. In addition, some other phases (particularly phases with Zr or Ti as stoichiometric constituents) have strong affinities for Hf (e.g., zircon, baddeleyite, rutile), which make them useful in tracer isotopic studies – especially when used in conjunction with the U-Pb geochronologic information from these mineral phases.

Although the Lu-Hf system was introduced to the geochemical and cosmochemical communities in the 1980s, analytical challenges limited the widespread use of this technique until the late 1990s. The reason for this is that Hf has a very high first ionization potential (6.83 eV, Lide 2003), which prevented easy and routine analysis of Hf isotopes using thermal ionization mass spectrometry (TIMS). As a result there were only a few practitioners using this system in the 1980s and much of the 1990s. These difficult analyses utilized specialized techniques and required considerable amounts of Hf for the analyses to be successful. This all changed with the advent and development of the multi-collector inductively coupled plasma mass spectrometer (MC-ICPMS), which combined the efficient ionization of Hf using an ICP ionization source with the high precision analysis afforded by multi-collector mass spectrometry (Blichert-Toft et al. 1997; Walder and Freedman 1992). This revolutionized the use of the Lu-Hf isotope system for geochronology and tracer isotope applications by allowing the routine analysis not only of Hf isotopes in general but also of much smaller amounts of Hf. This made several important things possible. *First*, it allowed for the more precise and accurate determination of the ^{176}Lu decay constant (Scherer et al. 2001; Söderlund et al. 2004). *Second*, the new MC-ICPMS instrumentation also facilitated the analysis of high Lu-Hf, but Hf-poor, phases like garnet or apatite, which made the use of these phases for geochronology possible. *Third*, it also made it possible to analyze Hf-poor rocks such as chondritic meteorites, which allowed more accurate constraints to be placed on the chondritic Lu-Hf value (e.g., Bouvier et al. 2008). *Finally*, MC-ICPMS technology has made it possible to determine the Lu-Hf isotope composition in very small, Hf-rich phases such as zircon. This latter application, particularly when done in conjunction with U-Pb geochronology, has enjoyed an explosion of use in recent years (e.g., Amelin et al. 2000; Fisher et al. 2014; Gerdes and Zeh 2009; Kemp et al. 2010; Woodhead et al. 2004; Xie et al. 2008; Yuan et al. 2008).

Background

Lutetium is the heaviest of the rare-earth elements (REEs) and shares a +3 valence with the lanthanides as a whole. It also has an odd atomic number (odd number of protons; $Z = 71$), which, in part, makes it the least abundant of the REEs (67 ppb; McDonough and Sun 1995). Lu has two isotopes (Table 1): ^{175}Lu is stable, is an odd-even nuclide, and is the most abundant isotope (97.4 %); ^{176}Lu is an odd-odd nuclide, has low abundance (2.6 %), and is radioactive, decaying primarily to ^{176}Hf by beta decay. A small percentage (<3 %) of ^{175}Lu is reported to decay to ^{176}Yb by electron capture (Dixon et al. 1954) although Amelin and Davis (2005) establish an upper limit of 0.9 % based on combined electron capture and positron emissions.

Hafnium is the next higher element from Lu on the periodic table ($Z = 72$) and is a high-field-strength element (HFSE) sharing geochemical similarities with other Group IVB elements, most

notably Zr and Ti. It is relatively under-abundant in the Earth (0.28 ppm, McDonough and Sun 1995) but enriched in the continental crust (5.3 ppm, Rudnick and Gao 2003). It has six isotopes, five of which are stable (Table 1). One isotope, ¹⁷⁶Hf (5.20 %), is radiogenic and produced, in part, by beta decay of ¹⁷⁶Lu and, together with ¹⁷⁶Lu, provides the basis of the Lu-Hf chronometer. By convention the reference stable isotope for the Lu-Hf system is ¹⁷⁷Hf (18.60 %).

In order to determine accurate Lu and Hf concentrations and, most importantly, the precise ¹⁷⁶Lu/¹⁷⁷Hf ratios required for geochronology and calculating accurate initial ratios, the “isotopic dilution” technique is required. This technique involves the addition of measured amounts of tracers of known isotopic composition (highly enriched in ¹⁷⁶Lu and ¹⁸⁰Hf, typically, with some labs using ¹⁷⁸Hf). These tracers, or “spikes,” are generally mixed and precisely calibrated so that evaporative loss will not affect the precise determination of the parent/daughter ratios. These spikes are added to the sample solution following or during dissolution, equilibrated with the solution, and become part of the isotopic mixture of the sample. Ultimately the ¹⁷⁶Lu/¹⁷⁷Hf and ¹⁸⁰Hf/¹⁷⁷Hf ratios of the samples are measured to determine Lu and Hf concentrations and precise Lu/Hf ratios.

In order to correct for mass dependent fractionation during mass spectrometry (i.e., mass bias), the convention for the Hf isotope system is to normalize to ¹⁷⁹Hf/¹⁷⁷Hf = 0.7325 (Patchett and Tatsumoto 1980b), the value that has been used since the early days of Hf isotope analyses. Mass bias for Lu isotopic analyses is complicated by virtue of the fact that Lu has only two isotopes, making internal normalization impossible. In the early TIMS era of Lu-Hf isotope measurements, the small degree of mass bias (~ 0.1 % per amu) was not as significant for the less stringent requirements of the Lu isotope dilution analysis. With the advent of the MC-ICPMS analyses, however, mass fractionation that is over an order of magnitude larger than TIMS necessitated an accurate mass bias correction. The current approach is to use a different element with at least one invariant isotope ratio and which has a similar mass bias response, such as Yb, to correct for mass bias in the Lu isotopic measurement. Because of the similarity of behavior of the REEs (particularly for adjacent REEs), it is often difficult to quantitatively remove Yb from Lu. The current practice employed in most labs is to remove the majority of the Yb (recall that Yb is an even element and so is much more abundant than the odd numbered Lu) and use the Yb isotope measurements to determine the mass bias and then apply this to the Lu measurement. This approach is somewhat complicated by the uncertain isotopic composition of Yb (e.g., Amelin and Davis 2005; Chu et al. 2002; Segal et al. 2003; Vervoort et al. 2004) and the fact that ¹⁷⁶Yb is a relatively abundant isotope (12.70 %) with the same mass as the ¹⁷⁶Lu spike. The interference of ¹⁷⁶Yb on the spike isotope, ¹⁷⁶Lu, requires that most of the Yb be removed from the sample. In detail there are probably small differences in the mass bias of Yb and Lu, and there are approaches to quantify these differences

(e.g., White et al. 2000). Despite all of these challenges, $^{176}\text{Lu}/^{177}\text{Hf}$ ratios in rock samples can probably be determined to ~0.2 % accuracy (Vervoort et al. 2004).

The Hf solution standard employed throughout the history of Hf isotope analysis has been JMC-475, a Hf metal obtained from Johnson Matthey Corporation (Patchett and Tatsumoto 1980b) with a currently accepted $^{176}\text{Hf}/^{177}\text{Hf}$ value of 0.282160 (Vervoort and Blichert-Toft 1999). The JMC-475 Hf standard solution is available from the author on request.

Decay System Fundamentals

Lutetium-176 decays to ^{176}Hf by beta decay with a half-life of 37.12 Ga:

Only a small percentage (~1 %) of ^{176}Hf in rocks and minerals is radiogenic and produced in this way; the majority of ^{176}Hf is “common” Hf, produced primarily during nucleosynthesis. The radiogenic decay equation for the Lu-Hf isotope system describes how radiogenic ^{176}Hf in a rock or mineral will evolve over time:

$$^{176}\text{Hf}_{(p)} = ^{176}\text{Hf}_{(t)} + ^{176}\text{Lu}_{(p)} * (e^{\lambda t} - 1).$$

This expression shows that the ^{176}Hf present in a given sample today is a function of (1) the ^{176}Hf in that sample at some time, t , in the past; (2) the amount of radiogenic ^{176}Lu in that material; (3) the amount of time elapsed since formation; and (4) the decay constant. In practice, we reference these isotopes to ^{177}Hf , a stable isotope of Hf. Thus the equation above becomes:

$$^{176}\text{Hf}/^{177}\text{Hf}_{(p)} = ^{176}\text{Hf}/^{177}\text{Hf}_{(t)} + ^{176}\text{Lu}/^{177}\text{Hf}_{(p)} * (e^{\lambda t} - 1).$$

Therefore, the material with high Lu/Hf ratios, such as garnet, will generate proportionally more ^{176}Hf over time and evolve to higher $^{176}\text{Hf}/^{177}\text{Hf}$ ratios. Conversely, the material with low Lu/Hf ratios, such as zircon, will produce proportionally little ^{176}Hf with time and so its $^{176}\text{Hf}/^{177}\text{Hf}$ ratios will increase only very slowly.

An important part of using these radiogenic equations for geochronology and for determining precise initial isotopic compositions is not only measuring the present-day ratios accurately but also knowing the decay constant precisely and accurately. The ^{176}Lu decay constant has been a source of uncertainty, however, and this has limited the full application of the Lu-Hf isotope system. The first determination of the ^{176}Lu decay constant for use in geochemistry and cosmochemistry was performed by Patchett and Tatsumoto (1980a) who determined an isochron on a collection of basaltic and cumulate eucrite meteorites. Using a presumed age of 4.55 Ga for the differentiation event for the eucrites, they determined a value for $\lambda^{176}\text{Lu}$ of $1.962 \pm 0.081 * 10^{-11} \text{ year}^{-1}$ with a corresponding half-life of 35.3 Ga. This value was later revised by Patchett (1983b) to $\lambda^{176}\text{Lu} = 1.94 \pm 0.07 * 10^{-11} \text{ year}^{-1}$ and a half-life of $35.7 \pm 1.4 \text{ Ga}$. This revised value was similar to a decay constant value of $1.93 \pm 0.03 * 10^{-11} \text{ year}^{-1}$ determined by physical counting experiments (Sguigna et al. 1982). The agreement between these results led, in part, to the use of the $\lambda^{176}\text{Lu}$ value of $1.94 \pm 0.07 * 10^{-11} \text{ year}^{-1}$ throughout the 1980s and much of the 1990s, with later studies (e.g., Blichert-Toft and Albarède 1997 and subsequent papers) using the Sguigna et al.’s

(1982) values. This early history of ^{176}Lu decay constant determinations is reviewed more thoroughly by Begemann et al. (2001).

The value determined for $\lambda^{176}_{\text{Lu}}$ changed dramatically following age comparison studies by Scherer et al. (2001) and Söderlund et al. (2004). Scherer et al. (2001) suggested a $\lambda^{176}_{\text{Lu}}$ value of $1.865 \pm 0.015 * 10^{-11} \text{ year}^{-1}$ based on the age comparisons of 4 samples from diverse localities and with different ages. This included two pegmatites from Norway with ages ~ 1.1 and 0.9 Ga, an apatite-xenotime bearing gneiss from New York State with an age of ~ 1.0 Ga, and a carbonatite from South Africa with an age of ~ 2.1 Ga. The U-Pb crystallization ages for these samples were based on the measurements of gadolinite, xenotime, baddeleyite, and apatite in these rocks; the Lu-Hf isochron was determined using the high Lu/Hf ratios of gadolinite, xenotime, and apatite combined with low Lu/Hf phases in the rock (baddeleyite, zircon, biotite) or the whole-rock compositions.

In a similar study, Söderlund et al. (2004) determined a $\lambda^{176}_{\text{Lu}}$ value of $1.867 \pm 0.008 * 10^{-11} \text{ year}^{-1}$ based on age comparisons using two Proterozoic dolerite dikes from Sweden. The ages of these rocks were determined using baddeleyite U-Pb geochronology; apatite was the high Lu/Hf phase providing the spread in the Lu-Hf isochron. Additional determinations by Scherer et al. (2003) agreed with the slightly faster decay of Söderlund et al.'s (2004) value. As a result of this agreement, the isotopic community is now using the $\lambda^{176}_{\text{Lu}}$ value of $1.867 \pm 0.008 * 10^{-11} \text{ year}^{-1}$. The half-life corresponding to this value is 37.12 Ga. The revision in the value for the ^{176}Lu decay constant from the Patchett (1983b) and Sguigna et al.'s (1982) values has two important consequences for Lu-Hf geochronology and isotope geochemistry. The first, and most obvious of these, is the change in calculated Lu-Hf ages. Using the Scherer/Söderlund decay constant results in ages that are 4 % older than ages determined with the Patchett/Sguigna value. The second consequence is that this lowers the calculated initial $^{176}\text{Hf}/^{177}\text{Hf}$ of rocks. The degree of this effect is a function of age but also of the $^{176}\text{Lu}/^{177}\text{Hf}$ ratios. For Archean and older samples, the lowering of the calculated initial $^{176}\text{Hf}/^{177}\text{Hf}$ for the Earth's oldest rocks has very significant implications for the record of the Hf isotope evolution of the Earth (e.g., Scherer et al. 2001, 2007).

Although the Söderlund/Scherer decay constant determinations, which used terrestrial samples in their age comparisons, have converged on a well constrained value of $1.867 \pm 0.008 * 10^{-11} \text{ year}^{-1}$, age comparison determinations based on meteorites continue to yield a faster ^{176}Lu decay rate. Blichert-Toft et al. (2002) reanalyzed a suite of basaltic and cumulate eucrites and concluded that their regression was consistent with the $1.93 \pm 0.03 * 10^{-11} \text{ year}^{-1}$ value of Sguigna et al. (1982) and not the slower decay rates determined from terrestrial age comparisons. As was true with the earlier work of Patchett and Tatsumoto (1980a), however, the basaltic and cumulate eucrites plot at opposite ends of the isochron with the basaltic eucrites at the low Lu-Hf end and the cumulate eucrites at the high Lu-Hf end, which may indicate these are not truly cogenetic. Further, these samples appear to have different formation ages with the cumulate eucrites arguably younger (Mittlefehldt et al. 1998). In another study using meteorite age comparison, Bizzarro et al. (2003) determined a $\lambda^{176}_{\text{Lu}}$ value of $1.983 \pm 0.033 * 10^{-11} \text{ year}^{-1}$, even faster than the Patchett/Sguigna values. The Bizzarro et al. (2003) study included analyses of ordinary chondrites, carbonaceous chondrites, and basaltic eucrites and used a common age of 4.56 Ga. As was true with the eucrite-based determination, this study included a diverse suite of meteorites of potentially different ages and metamorphic histories, and therefore, the decay constant determination may be affected in some way by the use of samples that do not strictly meet the requirements for an isochron. These caveats notwithstanding, there are indications that meteorite isochrons yield a faster decay constant. One possible explanation for this apparent difference between the terrestrial and meteorite determinations is the presence of excess ^{176}Hf in meteorites. This may have been produced by excitation of the long-lived radioactive isotope ^{176}Lu to a short-lived ^{176}Lu isomer early in the history of the solar

system that then decays quickly to ^{176}Hf , thereby producing the excess ^{176}Hf (Albarède et al. 2006; Thrane et al. 2010). The exact mechanism of how this might have occurred is still a matter of debate (Albarède et al. 2006; Thrane et al. 2010).

The Lu-Hf Isochron Method

All Lu-Hf geochronology uses the “isochron” method to determine absolute ages. Unlike some chronometers such as U-Pb in zircon where there is little, if any, daughter isotope at the time of mineral growth, in the Lu-Hf system, there is invariably an abundance of daughter isotopes present (i.e., “common Hf”). For this reason, it is not possible to determine the age of a single mineral sample by measuring the accumulation of daughter isotopes in the sample. Thus all Lu-Hf geochronometry relies on the isochron approach, which utilizes coexisting rocks and minerals to determine an age. Important assumptions in this approach include the following: (1) All the minerals formed at the same time (i.e., have the same age); (2) all samples are cogenetic (have the same isotopic composition at the time of formation); and (3) the sample being dated has been a closed system since the time of mineral growth.

The systematics of the Lu-Hf isochron method, using garnet geochronology as an example, is shown in Fig. 1: (1) Prior to mineral formation, whether in a magma or metamorphic protolith, the bulk rock has a low Lu/Hf ratio and (at least approximately) a uniform Hf isotopic composition at the hand sample scale. (2) During crystallization, or, in this example, metamorphism, different phases form with different Lu/Hf ratios, but all with the same initial $^{176}\text{Hf}/^{177}\text{Hf}$. (3) Over time, the Hf isotopic compositions of the different components evolve as a function of their Lu/Hf ratios with high Lu/Hf components evolving more quickly to elevated $^{176}\text{Hf}/^{177}\text{Hf}$ and low Lu/Hf components evolving more slowly. (4) At some later time, if the rock has been a closed system with respect to Lu and Hf, all components will have compositions that plot along a line that is a function of time.

Fig. 1 The isochron method applied to garnet Lu-Hf geochronology. (1) uniform Hf isotopic composition at time $t = 0$; (2) phases in rock acquire different Lu/Hf ratios (garnets with high Lu/Hf), but all with the same $^{176}\text{Hf}/^{177}\text{Hf}$; (3) Hf isotopic compositions of the different components evolve with time as a function of their Lu/Hf ratios; (4) if the rock has remained a closed system with respect to Lu and Hf, all components will plot along a line (isochron) that is a function of time

Regression of a line through these points yields a slope from which an age can be calculated using the formula:

$$\text{Age} = \ln(\text{slope} + 1) / \lambda^{176}_{\text{Lu}}.$$

In detail, many of the assumptions of the garnet isochron method are not strictly met. In most cases the rock is certainly not in perfect isotopic equilibrium (i.e., homogeneous $^{176}\text{Hf}/^{177}\text{Hf}$) prior to metamorphism. In addition, the time different phases in the rock form may not be precisely the same, especially in the case of prolonged garnet growth (e.g., Kohn 2009). These can be serious obstacles if there is a small range of Lu/Hf and $^{176}\text{Hf}/^{177}\text{Hf}$ variations in samples but are often overcome in isochrons with high Lu/Hf phases and large amounts of radiogenic Hf ingrowth.

Geochronologic Applications

Whole-Rock Lu-Hf Isochrons

Because of the limited fractionation in Lu/Hf that occurs during magmatic processes, there is rarely a sufficiently large range in Lu/Hf ratios in suites of rocks that are truly cogenetic to generate an isochron with enough precision to be useful (Patchett 1983b). If there is a large variation in Lu/Hf in a suite of samples, it is likely these samples are probably not strictly cogenetic. Examples of the former may be represented by the eucrite isochrons combining both basaltic and cumulate eucrites (Blichert-Toft et al. 2002; Patchett 1983b) and in the collective chondrite-eucrite isochron of Bizzarro et al. (2003). In practice, therefore, Lu-Hf whole-rock isochrons are rarely employed for geochronology, especially for terrestrial samples.

Apatite Lu-Hf Geochronology

There is potential in some magmatic rocks, however, to crystallize a high Lu/Hf phase (e.g., apatite, magmatic garnet) that can then be used in geochronology. The magmatic rocks that have the most promise for useful geochronometry are those that contain apatite as a crystallizing phase. As demonstrated by the decay constant work of Scherer et al. (2001) and Söderlund et al. (2004) and the pioneering work applying Lu-Hf geochronology to phosphates by Barfod et al. (2003), apatite generally has very high Lu/Hf ratios and can be used in generating meaningful isochrons. In addition, these phases are likely in isotopic equilibrium with the magma at the time of their formation and likely formed at the same time as the other phases in the rock. Furthermore, apatite can occur in mafic rocks that generally lack zircon and that may not contain baddeleyite. The potential of Lu-Hf apatite geochronology for providing important geochronologic information for some rocks that are notoriously difficult to date is high, and this should be a growth area in the future.

Garnet Lu-Hf Geochronology

The most successful geochronologic application of the Lu-Hf system has been garnet geochronology. This technique shares the same principles as Sm-Nd garnet geochronology in that it utilizes garnet's generally high affinity for HREEs which results in elevated Sm/Nd ratios and (generally higher) Lu/Hf ratios in the garnets as they grow. The potential of the garnet Lu-Hf technique was first demonstrated by a number of papers in the late 1990s (Blichert-Toft et al. 1999; Duchene et al. 1997; Scherer et al. 1997). Following this early proof-of-concept work, there have been a large number of studies in a wide variety of metamorphic rocks: garnet-bearing pelitic schists, para- and orthogneisses, amphibolites, eclogites, and granulites (Anczkiewicz et al. 2004; Bird et al. 2013;

Cheng et al. 2008; Herwartz et al. 2011; Kelly et al. 2011; Scherer et al. 2000; Smit et al. 2013; Wells et al. 2012; Zirakparvar et al. 2010). Reliable garnet Lu-Hf ages have been reported for rocks as old as Archean (e.g., Smit et al. 2013) and as young as Miocene (e.g., Zirakparvar et al. 2011) and everything in between.

Although there are many parallels between Lu-Hf and Sm-Nd garnet geochronology, there are important differences between these two systems. *First*, the decay rate of the parent isotope in the Lu-Hf system, ^{176}Lu , is ~ 3 times faster than ^{147}Sm in the Sm-Nd system. This results in a higher rate of ingrowth in the radiogenic daughter, ^{176}Hf , compared to ^{143}Nd . *Second*, owing to the different geochemical behavior between a REE and a HFSE, there is generally more fractionation in the Lu/Hf ratios compared to Sm/Nd, which is especially manifest in phases like garnet and apatite.

Third, Lu is partitioned into garnet most strongly of all the REEs, while Hf is incorporated into garnet only weakly (Table 2). This often results in pronounced Lu-Hf zoning in the garnet with high Lu/Hf ratios in the core, due to the strong incorporation of Lu during early garnet growth, and with lower Lu/Hf ratios toward the rim due to the depletion of Lu in the garnet feeding zones. Because the very high Lu-Hf in the cores will exert a strong control on the slope of the regression, it has been suggested that Lu/Hf ages will be biased toward the early stages of garnet growth (Lapen et al. 2003; Skora et al. 2006). In this way, we would expect slightly older Lu-Hf garnet ages compared with Sm-Nd ages in a slowly growing garnet (Lapen et al. 2003; Skora et al. 2006).

Fourth, there are significant differences in the apparent closure temperature ranges in garnet between the two isotopic systems with garnets closing for Lu-Hf at a higher temperature than for the Sm-Nd system. Debate continues on closure temperature estimates of the Sm-Nd chronometer (e.g., Dutch and Hand 2009; Ganguly et al. 1998; Scherer et al. 2000; Smit et al. 2013; Van Orman et al. 2002), but appear to be in the range of ~ 700 – 750 °C for garnets 1 mm diameter and larger (Smit et al. 2013; Van Orman et al. 2002) and significantly higher (perhaps 100 °C or more) for Hf. This can lead to differences between the garnet Lu-Hf and Sm-Nd ages with the Lu-Hf ages

Table 2 Melt-solid partition coefficients for Lu and Hf in various minerals

Mineral	D(Lu)	D(Hf)	Melt	References
Olivine	0.0015	0.01	Basalt	McKenzie and O’Nions 1991

Garnet	23.5	3.3	Dacite	Irving and Frey 1978
Apatite	13.8	0.73	Andesite	Bacon and Druitt 1988
Apatite	21.5	0.878	Dacite	Fujimaki 1986
Zircon	196	958	Andesite	Fujimaki 1986
Zircon	689	971	Dacite	Fujimaki 1986

The partition coefficient, D, is defined as the ratio of the concentration of the element in the solid compared to melt. Values are from GERM database (<http://earthref.org/KDD/>) compiled from the original references listed above

systematically older (e.g., Scherer et al. 2000). In some granulite terranes that may have remained buried at mid- to lower-crustal levels for a prolonged time during and following garnet growth, these age differences can be large – as much as 50–70 m.y. (Smit et al. 2013; Vervoort et al. 2013). Experimental work also indicates significantly slower diffusion for Hf in garnets than the REEs (Ganguly et al. 2010), which collectively have similar diffusion rates. One possible consequence of the slower diffusion of Hf than Lu is that the garnet may effectively close to Hf diffusion before Lu, leading to changing Lu/Hf ratios, but static Hf isotopic compositions (Ganguly et al. 2010). This could potentially result in “isochron rotation” and garnet Lu-Hf ages that are artificially too old.

Finally, the presence of accessory phases (e.g., zircon, apatite, monazite, allanite), especially as inclusions in the garnets, presents a special challenge (e.g., Anczkiewicz and Thirlwall 2003; DeWolf et al. 1996; Prince et al. 2000; Scherer et al. 2000; Thoni 2002), and each of these minerals affects the Lu-Hf and Sm-Nd system in different ways. For the Lu-Hf system, zircons provide the biggest challenge. Zircons are extraordinarily enriched in Hf (~10,000 ppm Hf in zircon) relative to garnet ($\ll 1$ ppm) and, therefore, can easily overwhelm Hf concentration budget if present as inclusions in the garnets, thus lowering Lu/Hf ratios of the garnet dissolutions. Furthermore, inclusions of preexisting zircons, which are not likely to be re-equilibrated prior to metamorphic growth, can significantly lower the measured $^{176}\text{Hf}/^{177}\text{Hf}$ of the garnet sample since these zircons will have a less radiogenic Hf isotopic composition than the bulk rock. If these zircons are much older than the bulk rock, this difference can be significant. The incorporation of zircon Hf not in isotopic equilibrium with the protolith at the time of metamorphism in the analyses, either in garnet or as a dispersed accessory phase in the rock matrix, can result in erroneous ages (e.g., Scherer et al. 2000). Fortunately, what makes zircon resistant to isotopic equilibration during metamorphism also makes it resistant to dissolution, and thus zircon inclusions can be largely avoided with a nonaggressive dissolution protocol (e.g., Cheng et al. 2008; Lagos et al. 2007). Very high $^{176}\text{Lu}/^{177}\text{Hf}$ ratios (generally $\gg 1$) in the garnet analyses is an indication that zircon (very low $^{176}\text{Lu}/^{177}\text{Hf}$ ratios, usually 0.002 to 0.001) has not been significantly dissolved. Apatite inclusions (very high $^{176}\text{Lu}/^{177}\text{Hf}$ ratios) in the garnet can also potentially have an effect on an isochron if they either are not in isotopic equilibrium with the garnet at the time of metamorphic growth or are formed or closed to Lu-Hf diffusion at a different time than the garnet. The effect of apatite inclusions on garnet Lu-Hf geochronology, however, has not yet been examined in the literature. For the Sm-Nd isotope system, the inclusions that are most problematic are phases enriched in REEs and with low Sm/Nd ratios such as monazite and allanite. The effect of these inclusions is generally to drastically reduce the spread in the isochron. If present within the garnets and incorporated in the dissolution, the garnets will have low Sm/Nd ratios – often as low as the whole rock – thus eliminating the possibility of producing a meaningful isochron.

Lawsonite Lu-Hf Geochronology

A recent addition to the Lu-Hf geochronology toolbox is the use of the mineral lawsonite to date subduction zone processes (Mulcahy et al. 2009; Vitale Brovarone and Herwartz 2013). Depending on its paragenesis, lawsonite can have sufficiently elevated Lu/Hf ratios to produce meaningful isochrons. Lawsonite is an important index mineral formed during low temperature-high pressure subduction zone metamorphism and potentially provides one of the few tools we have available to date subduction zone processes. Initial work with this geochronologic tool has shown that when lawsonite forms on the retrograde path from the breakdown of garnet, it generally has elevated Lu/Hf

ratios and can yield robust Lu-Hf ages. When the lawsonite forms from the breakdown of zeolites on a prograde path, however, it may not develop elevated Lu/Hf ratios and, therefore, may not provide useful Lu-Hf ages (Mulcahy et al. in review). The full potential of this geochronologic tool is just now being explored.

Hf Radiogenic Isotope Geochemistry

As mentioned above, both Lu and Hf are lithophile and refractory elements with high condensation temperatures. Because of these characteristics, it has long been assumed that the abundance of these elements in the bulk Earth can be approximated by chondritic meteorites. It has also been long assumed that the isotopic composition of a refractory element such as Hf was homogeneous in the solar nebula and can also be approximated by chondritic meteorites. This is known as the Chondritic Uniform Reservoir model, or CHUR. Recent work, primarily based on the short-lived ^{146}Sm - ^{142}Nd isotopic system, has questioned whether the Earth is strictly chondritic in composition (see discussion in Sm-Nd section). Regardless of whether the Earth is strictly chondritic, the CHUR model provides an important reference value for a plausible bulk Earth composition. The Lu-Hf and Sm-Nd systems are used in tandem for planetary evolutionary studies for the important reason that these are the only two such isotopic systems in which all elements are lithophile and refractory.

The Bulk Silicate Earth and CHUR

Because of the analytical challenges in measuring Hf isotope compositions in Hf-poor (~ 0.10 ppm; McDonough and Sun 1995) chondrites accurately and precisely, the early Lu-Hf CHUR values had considerable uncertainty. There have been two approaches used to determine a CHUR value for the Lu-Hf and Sm-Nd isotope systems. For Sm-Nd, because there is very little fractionation between Sm and Nd in chondrites and there are no phases with low Sm/Nd ratios, it has not been possible to determine a chondritic (Solar System) initial value for this system. Instead, the approach has been to take an average of representative present-day $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{147}\text{Sm}/^{144}\text{Nd}$ values of undifferentiated chondrites. This works because the total Sm-Nd variation in chondrites is modest. Using this approach, Jacobsen and Wasserburg (1980, 1984) determined present-day CHUR values of $^{143}\text{Nd}/^{144}\text{Nd} = 0.512638$ and $^{147}\text{Sm}/^{144}\text{Nd} = 0.1966$, which corresponded to the composition of two CI chondrites, Allende and Murchison.

The situation for the Lu-Hf isotope system was initially different because of the difficulty in measuring Hf precisely in the Hf-poor chondrites and the large apparent spread in $^{176}\text{Lu}/^{177}\text{Hf}$ and $^{176}\text{Hf}/^{177}\text{Hf}$ in chondrites, which makes determining a mean chondritic value more ambiguous. In order to compare this system to the more established Sm-Nd isotope system, Patchett and Tatsumoto (1981) based the Hf CHUR values on the same CI chondrites used to define the Sm-Nd isotope system, Allende and Murchison. Using this approach, they arrived at present-day values of $^{176}\text{Hf}/^{177}\text{Hf} = 0.282860$ and $^{176}\text{Lu}/^{177}\text{Hf} = 0.0334$. The $^{176}\text{Hf}/^{177}\text{Hf}$ value was later adjusted to 0.282830 (Vervoort and Patchett 1996) to account for the high $^{176}\text{Hf}/^{177}\text{Hf}$ bias on the TIMS in Denver, the instrument on which all the early pioneering Hf isotope work was performed.

With the advent of the MC-ICPMS and its application to measuring Hf isotopes came the ability to analyze Hf-poor chondrites more precisely. In order to constrain the Lu-Hf CHUR values, Blichert-Toft and Albarede (1997) analyzed 25 chondritic meteorites including carbonaceous, ordinary, and enstatite chondrites. Because the measured values of these samples had a wide spread in $^{176}\text{Hf}/^{177}\text{Hf}$ and $^{176}\text{Lu}/^{177}\text{Hf}$ ($\sim 18\%$) and did not define an isochron, they took the weighted average of the 25 chondrites to arrive at present-day values of $^{176}\text{Hf}/^{177}\text{Hf} = 0.282772$ and $^{176}\text{Lu}/^{177}\text{Hf} = 0.0332$.

The $^{176}\text{Hf}/^{177}\text{Hf}$ values were significantly lower by 0.000058 from the adjusted Patchett and Tatsumoto values (Vervoort and Patchett 1996).

In order to address the problem of the spread in Lu/Hf ratios and the scatter about a reference isochron, Bouvier et al. (2008) analyzed only unequilibrated chondrites (lower metamorphic grade, petrologic types 1–3) including 12 carbonaceous chondrites, 13 ordinary chondrites, and 3 enstatite chondrites. The resulting data had a much smaller spread in Lu/Hf ratios (only 3 %) which allowed a more precise determination of the present-day CHUR values: $^{176}\text{Hf}/^{177}\text{Hf} = 0.282785 \pm 11$ and $^{176}\text{Lu}/^{177}\text{Hf} = 0.0336 \pm 1$. These are the values currently in use by the geochemical and cosmochemical communities. Bouvier et al. (2008) also measured the Sm-Nd isotopic compositions of the same solutions on which the Lu-Hf values were determined and arrived at new CHUR values for the Sm-Nd isotope system of $^{143}\text{Nd}/^{144}\text{Nd} = 0.512630$ and $^{147}\text{Sm}/^{144}\text{Nd} = 0.1960$. Although these are very close to the values of Jacobsen and Wasserburg (1980, 1984), the Bouvier et al.'s (2008) values are more appropriate to use in studies reporting both Hf and Nd data relative to the chondritic reference because they represent values determined on the same set of chondrites.

As is true for the Sm-Nd system, Hf isotope data are often expressed in epsilon values, which are variations in parts per 10,000 from the CHUR reference. Expressed in terms of present-day compositions, this expression is:

$$\varepsilon_{\text{Hf}(0)} = \left[\left(^{176}\text{Hf}/^{177}\text{Hf}_{(\text{sample},0)} - ^{176}\text{Hf}/^{177}\text{Hf}_{(\text{chur},0)} \right) / \left(^{176}\text{Hf}/^{177}\text{Hf}_{(\text{chur},0)} \right) \right] \times 10^4.$$

Expressed in terms of compositions at any time in the past, t , this expression is:

$$\varepsilon_{\text{Hf}(t)} = \left[\left(^{176}\text{Hf}/^{177}\text{Hf}_{(\text{sample},t)} - ^{176}\text{Hf}/^{177}\text{Hf}_{(\text{chur},t)} \right) / \left(^{176}\text{Hf}/^{177}\text{Hf}_{(\text{chur},t)} \right) \right] \times 10^4.$$

Frequently, when values are calculated back in time, they are expressed as “initial” values, signifying the formation age of that rock or mineral. (It is important to note that the CHUR value also needs to be calculated back to its composition at time, t , from the present-day values.)

Lu-Hf Tracers of Geologic Processes

The current paradigm for the evolution of the Earth holds that the crust was formed from silicate melts extracted in some way from the mantle. The crustal rocks resulting from this process are enriched in incompatible elements (hence the term enriched crust), and the mantle left from this extraction of crust is depleted in incompatible elements (hence the term depleted mantle). As a consequence of this differentiation occurring throughout the history of the Earth, including at its very beginning, the Earth's different reservoirs have evolved following different paths. The crustal reservoirs are enriched in incompatible elements but have lower Lu/Hf and Sm/Nd ratios than bulk Earth, and so their $^{176}\text{Hf}/^{177}\text{Hf}$ and $^{143}\text{Nd}/^{144}\text{Nd}$ evolve more slowly. Conversely, the depleted mantle components, while depleted in incompatible elements, have higher Lu/Hf ratios and Sm/Nd ratios, and so their $^{176}\text{Hf}/^{177}\text{Hf}$ and $^{143}\text{Nd}/^{144}\text{Nd}$ compositions evolve more quickly than bulk Earth (Fig. 2a). In terms of epsilon values relative to bulk Earth (i.e., CHUR), depleted mantle components evolve toward positive epsilon values, and enriched crustal values evolve toward negative epsilon values (Fig. 2b). This is a fundamental feature in both the Hf and Nd isotopic records of Earth's evolution and has been used to great utility in a wide range of crust/mantle petrogenetic/geochemical studies.

Fig. 2 Schematic diagram showing the hypothetical Hf isotope evolution of different terrestrial reservoirs following a major differentiation event at 3.8 Ga: Chondritic Uniform Reservoir (CHUR) broadly taken as representative of bulk silicate Earth (BSE), depleted mantle evolution from depletion at 3.8 Ga to its composition today, evolution of an enriched crustal reservoir ($^{176}\text{Lu}/^{177}\text{Hf} = 0.015$), and evolution of a typical zircon formed at 3.8 Ga ($^{176}\text{Lu}/^{177}\text{Hf} = 0.001$). (a) Evolution of $^{176}\text{Hf}/^{177}\text{Hf}$. (b) The same diagram in epsilon Hf notation

An important component in all radiogenic isotopes is time; time is an inherent aspect of Hf isotope evolution and therefore Hf isotope compositions can be used to qualitatively assess the time of separation from different reference reservoirs. These time estimates are called “model ages” and, although not ages in the strict sense, are still a useful way to represent and visualize data with a temporal framework.

The concept of a model age in the Lu-Hf isotope system follows that of Sm-Nd model ages (DePaolo 1981) and is illustrated in Fig. 3a. The $^{176}\text{Hf}/^{177}\text{Hf}$ isotopic composition of a sample is measured today, and the $^{176}\text{Lu}/^{177}\text{Hf}$ ratio of that sample is used to calculate its isotopic composition back in time until it intersects with a reservoir of interest such as the depleted mantle. The time, corresponding to this intersection, is a Hf model age – in this case, the Hf depleted mantle model age $\text{Hf}_{\text{T(DM)}}$. This model age has also been termed a crust-formation age, $\text{Hf}_{\text{T(CR)}}$, signifying the average time since separation from the depleted mantle or time of residence in a crustal reservoir (DePaolo 1981).

Fig. 3 (a) Schematic diagram showing the calculation of Hf model ages for two hypothetical whole-rock (wr) samples that formed from a depleted mantle reservoir at ~2.7 Ga: a mafic sample with a high Lu-Hf ratio ($^{176}\text{Lu}/^{177}\text{Hf} = 0.025$) and a negative present-day epsilon Hf value of approx. -10 and a felsic sample with a low Lu-Hf ratio ($^{176}\text{Lu}/^{177}\text{Hf} = 0.010$) and a highly negative present-day epsilon Hf value of ~-38. Also shown in this diagram are the depleted mantle model ages (T_{DM}) and the CHUR model ages (T_{CHUR}). Note the different trajectories for the two samples and the differences in T_{CHUR} . (b) Schematic diagram showing the calculation of zircon Hf model ages. In this example the zircon has a present-day epsilon Hf value of ~-55 and an initial epsilon Hf value of ~-5 calculated at a crystallization age of ~2.2 Ga. Calculation of depleted mantle model ages (T_{DM}) requires an assumption of the $^{176}\text{Lu}/^{177}\text{Hf}$ of the source rock. If the source rock is more evolved ($^{176}\text{Lu}/^{177}\text{Hf} = 0.01$ in this case), the T_{DM} is ~2.85 Ga. If the source rock is more mafic ($^{176}\text{Lu}/^{177}\text{Hf} = 0.025$ in this case), the T_{DM} is much older, ~3.45 Ga. As can be seen from this diagram, the uncertainty in the T_{DM} increases dramatically the further the initial Hf value is away from the depleted mantle reference line. Further, unrecognized Pb loss in the zircon, which would yield anomalously young crystallization ages, exacerbates the difference between crystallization and depleted mantle ages. See text for further discussion of zircon Hf model ages

Depleted mantle model ages have been used to identify the sources of magmatic rocks; if the Hf T_{DM} values are older than the crystallization ages, then the interpretation is that these rocks were derived from older sources or sources that had a crustal prehistory – sources that had separated from the mantle some time in the past. In this way it is simply another means of conveying the Hf isotopic compositions in the context of time – in much the same way as an epsilon Hf isotope diagram places the Hf isotope compositions in a time context. Model ages are also applied to sediments to identify

the provenance of their sources: more juvenile mantle-derived sources, older evolved crustal sources, or some mixture of the two. This is identical to the approach used for Sm-Nd model ages in sediments with the caveat that Hf model ages are often more variable than Nd model ages because of the presence or absence of Hf-rich (and unradiogenic) zircons in the sediments (e.g., Prytulak et al. 2006; Vervoort et al. 1999).

A recent adaptation of Hf model ages – and one that has seen an explosion of use in recent years – is the use of Hf model ages of zircons. The way this works is shown in Fig. 3b. The Hf isotopic composition is measured in the zircon and the zircon's Lu/Hf ratio is used to calculate back to its crystallization age. At that point, the growth trajectory changes, assuming a source $^{176}\text{Lu}/^{177}\text{Hf}$ ratio. As was the case with the other model ages, the intersection with the depleted mantle reference line yields the zircon Hf depleted mantle model age. This technique has recently been applied to detrital zircon studies because of the facility of acquiring U-Pb crystallization ages and Lu-Hf isotope compositions on the same zircon grain by laser ablation-inductively coupled plasma mass spectrometry (LA-ICPMS).

There are several aspects of this approach, however, that result in considerable uncertainty in the zircon Hf model “ages.” Because the context of the rock has been lost, the Lu/Hf ratio of the zircon's precursor rock has to be estimated, and this value can vary widely from a mafic precursor (high Lu/Hf) to a felsic precursor (low Lu/Hf). The further the composition of a zircon is from the depleted mantle (or other) reference, the greater the uncertainty in the model age. Another limitation of this technique is that the model ages rely on the intersection of the zircon + precursor rock trajectory with a depleted mantle reference curve. The depleted mantle, however, is not a discrete entity with a discrete isotopic composition. It is, in fact, typically defined by its most depleted, rather than average, compositions (Vervoort and Blichert-Toft 1999). Finally, it is not possible to determine the true ages of some detrital zircons precisely, due to the potential for ancient Pb loss and other factors. If ancient Pb loss exists in these grains, this would greatly exacerbate the differences between the crystallization and the Hf model ages with the former being too young and the latter being too old. In total, all of these factors contribute to very large uncertainties in Hf model “ages.” It is tempting to treat these model ages, particularly for detrital zircons, as values with quantifiable age information rather than model-dependent estimates. It is important to recognize, however, that these model ages are not ages in any true sense of the word, but rather “models” with large uncertainties. While they provide some useful constraints on the timing and nature of crust forming events, it is imperative to understand the limitations of such “age” information.

Conclusions

The Lu-Hf isotope system is an important chronometer in geochemistry and cosmochemistry. Its utility as a chronometer in whole-rock samples, however, is limited by the relatively small degrees of Lu-Hf fractionation during magmatic processes. In rocks with high Lu-Hf phases, the Lu-Hf isotope system can be a powerful chronometer; this is especially true for garnet-bearing metamorphic rocks and magmatic rocks with apatite as a crystallizing phase.

There now appears to be widespread agreement on a value for the ^{176}Lu decay constant of $1.867 \pm 0.008 \times 10^{-11}$ Ga (Scherer et al. 2001; Söderlund et al. 2004). This value has important implications not only for Lu-Hf geochronology but also for early Earth differentiation and evolution based on calculated initial Hf isotope values. Similarly, there is currently widespread acceptance of the Bouvier et al. (2008) CHUR values of $^{176}\text{Hf}/^{177}\text{Hf} = 0.282785$ and $^{176}\text{Lu}/^{177}\text{Hf} = 0.0336$. Corresponding to these are the Sm-Nd CHUR values of $^{143}\text{Nd}/^{144}\text{Nd} = 0.512630$ and

$^{147}\text{Sm}/^{144}\text{Nd} = 0.1960$. Notwithstanding discussions of whether or not the Earth is strictly chondritic, these values provide a self-consistent baseline on which to reference the isotopic evolution of the Earth.

Tracer isotopic applications provide equal utility of the Lu-Hf isotopic system and, in conjunction with independent age information, can be used to determine the Hf isotopic composition of rocks and minerals back into time. This information is useful in constraining both the evolution and source regions of igneous systems as well as the provenance of sedimentary rocks. By far the most heavily utilized mineral for tracer isotope studies is zircon, which provides a unique opportunity for determining both age and Hf isotope compositions in individual crystals (and even separate growth zones within a single crystals), such as in the case of inheritance or overgrowths. For this reason, the integrated U-Pb and Hf isotope information from zircon has seen a rapid increase in use in recent years and will likely continue. Many of these studies often report zircon Hf model ages. While these provide useful qualitative, model-based data, these are not in any way truly ages and should not be interpreted as containing quantitative chronologic information.

In summary, with the full implementation of techniques and applications of the Lu-Hf isotope system following the advent of MC-ICPMS technology, Lu-Hf geochronology and tracer isotope work has finally taken its place at the table with the other main players in geochronology and radiogenic isotope geochemistry.

Alpha Spectroscopy

Jeroen Thompson*

Department of Medical Physics and Applied Radiation Sciences, McMaster University, Hamilton, ON, Canada

Synonyms

[Alpha counting](#); [Thick source alpha counting](#)

Definition

Measurement of U and Th concentrations in environmental samples through detection of alpha particles emitted by isotopes in the U and Th decay chains.

Alpha particles emitted during radioactive decay are extremely short range (in minerals, micrometers) but deposit a significant quantity of energy. Therefore, the isotopes responsible for alpha emissions may be a large contributor to the overall absorbed radiation dose for a datable sample.

In order to measure the U and Th concentrations in a mineral, the sample is ground to a powder and deposited on a scintillator screen (mounted to a photomultiplier tube) or on to a semiconductor detector. Alpha particles deposit significantly more energy than beta particles or gamma rays, so unwanted counts are rejected through electronic processing of the signals recorded by the detector.

Although thin samples would provide better energy resolution (essentially no loss of energy due to alpha particle interactions within the sample), thick samples are preferred in order to achieve acceptable count rates. The sample thickness is therefore greater than the maximum range of the naturally emitted alpha particles (“thick source alpha counting”). Alpha dose rates are determined from the count rate, sample density, and average alpha particle range of all alpha emissions in a given decay chain (Aitken [1985](#)).

U and Th concentrations may be determined through other techniques, such as instrumental neutron activation analysis (INAA) or x-ray fluorescence (XRF). However, thick source alpha counting and high-resolution gamma spectroscopy permit the identification of disequilibria in the U and/or Th decay chains (Michael et al. [2008](#); Sjostrand and Prescott [2002](#)). This can result in more accurate alpha dose rate measurements.

Band Structure

Jeroen W. Thompson*

Department of Medical Physics and Applied Radiation Sciences, McMaster University, Hamilton, ON, Canada

Synonyms

[Electronic band structure](#)

Definition

Configuration of allowed and disallowed electron states. Crystals (structures consisting of regularly repeating units) typically have “energy bands” in which an electron may have any energy within a continuous, or nearly continuous, energy range. Energy bands are separated by “band gaps” which specify a range of energies which are impossible for an electron in that system to have.

A variety of models and mathematical tools can be used to determine the nature of a particular crystalline material’s electronic band structure from the basic principles of quantum mechanics. For discussion here, we will concern ourselves only with the highest-energy fully or partially occupied band (“valence band”) and lowest-energy unoccupied band (“conduction band”).

In an insulator, the ground state consists of a fully occupied valence band and an empty conduction band. The random excitations due to ambient temperatures are not sufficient to add enough energy to an electron so that it may occupy a state in the conduction band, where it is free to move. In contrast, the ground state of a metal consists of a partially occupied valence band. Here there is no energy gap, and even thermal excitations are sufficient to populate some higher-energy states in the valence, leaving behind unoccupied states of lower energy. Electrons may therefore absorb energy, be promoted to higher-energy states, move (conduct) through the crystal, and finally release energy when recombining with a so-called hole.

The physical basis of electron spin resonance, optically stimulated luminescence, and thermoluminescence dating (so-called “trapped charge” techniques) rely on defects in the otherwise perfect pattern of a crystal. These defects can introduce localized energy states in the band gap, and transitions between localized defect states and nonlocalized band states are responsible for the underlying physics of these techniques.

Beta Counter

Jeroen Thompson*

Department of Medical Physics and Applied Radiation Sciences, McMaster University, Hamilton, ON, Canada

Definitions

Beta counter: Instrument for the detection of beta particles and hence quantification of beta-emitting radioactive material.

Beta particle (b^-): Electron emitted from an atomic nucleus during a nuclear decay in which the atomic number (Z) increases by 1 (essentially, a proton is converted to a neutron with emission of an electron from the nucleus).

Proportional counter: A gas-filled radiation detector in which electrons are accelerated towards an anode, creating secondary ionization events in the gas, which in turn cause additional ionization events, etc. This cascade (Townsend avalanche; charge amplification) results in electronic pulses which are proportional to the energy originally deposited within the detector by ionizing radiation.

Liquid scintillation counter: A liquid-filled radiation detector in which a radioactive sample is dissolved into a liquid scintillator (typically based on an organic solvent such as toluene). Deposition of energy through ionizing radiation results in the emission of light by the liquid scintillator, with detection by one or more photomultiplier tubes.

Beta counters are used in “conventional” ^{14}C dating to measure the activity of ^{14}C . Regardless of detection technique, a measured count rate (decays/second [Bq] or equivalent) is related to quantity through the known half-life of ^{14}C .

Beta counting can also be used to directly measure environmental beta activity in luminescence dating dose rate determinations (Sanderson 1988; Roberts et al. 2003).

The relatively low energy of the beta particles emitted by ^{14}C requires attention to the detector counting efficiency. One approach is to convert the sample carbon to the gas CO_2 , which is mixed with a fill gas and introduced into a gas proportional counter. Alternately, the carbon can be converted to benzene and then mixed with a solvent and liquid scintillation cocktail for counting of light pulses emitted as a result of energy deposited by individual beta particles.

Electron Spin Resonance Spectrometer

Jeroen Thompson*

Department of Medical Physics and Applied Radiation Sciences, McMaster University, Hamilton, ON, Canada

Synonyms

Electron paramagnetic resonance spectrometer; EPR spectrometer; ESR spectrometer

Definition

Instrument for the detection of electron paramagnetic transitions, consisting of a tunable source of electromagnetic radiation, a resonant cavity, an electromagnet, and a detector.

The electron spin resonance (ESR) spectrometer is employed to detect electron paramagnetic resonance transitions. Although a wide variety of designs exist, the typical commercial continuous-wave spectrometer consists of (1) a microwave source tunable within a limited range of frequencies near 9.4 GHz; (2) a sample cavity, often cylindrical, capable of maintaining an electromagnetic standing wave; (3) an electromagnet capable of generating and ramping a uniform magnetic field, along with superimposed rapid oscillation up to 100 kHz in frequency; (4) a detection system which amplifies the reflected microwave signal; and (5) an internal magnetic field standard such as MnO.

Transitions between electronic energy levels may be induced by polarized electromagnetic radiation such that the energy of the incident radiation is equal to the difference in energy between the energy levels in question. In other words, the microwave source is used to generate a fixed energy (E) of incident radiation with frequency ν (where $E = h\nu$) which is reflected from the sample in the resonant cavity, and the energy reflected is recorded by the detector. The energy levels will vary with the strength of an external magnetic field. Therefore, “sweeping” the external magnetic field strength from low to high will allow for resonant transitions to occur at the appropriate combination of (fixed) microwave energy (frequency) and external magnetic field. Resonance involves a net absorption of incident energy, which is detected as a relative loss in reflected energy.

The faithful reproduction of any given resonant absorption signal requires careful attention to instrumental parameters, including (1) incident microwave power, (2) center field (magnetic field strength at the midpoint of the sweep), (3) scan width (range of the swept magnetic field), (4) modulation amplitude (amplitude of the superimposed 100 kHz oscillating magnetic field), (5) sweep time, (6) time constant (roughly, the characteristic time over which instrumental data is averaged), (7) number of sweeps, and (8) detector gain.

Radiation Defect

Jeroen Thompson*

Department of Medical Physics and Applied Radiation Sciences, McMaster University, Hamilton, ON, Canada

Definition

Radiation defects – These are divided into two types: (1) those produced by atomic displacements of normal lattice site elements during irradiation (intrinsic) which are later modified by ionizing radiation and (2) those created initially during growth of the crystal lattice by substitution of an impurity atom or molecule (extrinsic) that are later modified by ionizing radiation. These types of defects are radiation sensitive, that is, they accumulate with increasing levels of ionizing radiation.

Radiation defects are utilized in all forms of *trapped charge or radiation exposure dating*, i.e., thermoluminescence (TL), optically stimulated luminescence (OSL), electron spin resonance (ESR), and other less common techniques. Ionizing radiation from natural background sources creates ions and free electrons; these ions and/or electrons may be stabilized (trapped) as radiation-induced defects before recombination can occur at normal lattice sites. If a signal related to concentration of defects can be measured through a suitable technique (such as TL, OSL, or ESR) and if the signal can be related to the total absorbed radiation dose, then an age may be inferred from a measurement of signal intensity in combination with a determination of past radiation dose rate.

In many cases, the precise identity of the defect(s) responsible for a given dating signal may not be known.

One example of a known class of extrinsic radiation defects is the Al center. The parent center is an Al^{3+} ion substituting for Si^{4+} in quartz (crystalline SiO_2), accompanied by an interstitial cation M^+ for reasons of charge neutrality: $[\text{AlO}_4/\text{Li}^+]^0$, $[\text{AlO}_4/\text{Na}^+]^0$, and $[\text{AlO}_4/\text{H}^+]^0$ are neutral parent centers (Ikeya 1993). An electron released due to the action of ionizing radiation may result in a hole trapped at the Al defect site, with the cation diffusing away to form the stable radiation defect $[\text{AlO}_4/\text{h}]^0$. The concentration of Al defects may be determined through electron spin resonance spectroscopy at low temperatures (77 K).

An example of an intrinsic radiation defect is the E'_1 center in quartz. This is an oxygen vacancy charged with a single unpaired electron located on an adjacent silicon atom (Rudra and Fowler 1987).

Gene Sequencing

Jessica A Thomas*

Department of Biology, University of York, York, UK

Gene sequencing is the process of determining the order of nucleotides (adenine, guanine, cytosine, and thymine) in a strand of DNA. The resulting DNA sequences can be analyzed using phylogenetic methods, molecular clocks, and other techniques.

In living cells, DNA is copied by the enzyme DNA polymerase. The two strands of the DNA double helix, which are complementary to each other, are separated and used as templates. New DNA strands are synthesized by the sequential addition of nucleotides complementary to each strand.

The sequence of nucleotides in DNA can provide useful information for various biological analyses. Over the past few decades, the traditional method of determining DNA sequences in the laboratory has been the Sanger chain-termination method. This was developed by Frederick Sanger and colleagues in the late 1970s (Sanger et al. 1977). The method uses modified versions of the four nucleotides that terminate the extension of the new DNA strand and that are labelled with a nucleotide-specific fluorescent marker. Using a mixture of modified and regular nucleotides, DNA synthesis proceeds until a modified base is incorporated into the new DNA strand by chance. Each strand will terminate at a different nucleotide along the gene sequence, depending on the progress of DNA synthesis. At the end of the reaction, fragments are separated according to length and a laser determines the fluorescence of each fragment. This produces a series of fluorescence peaks, allowing the nucleotide sequence to be determined. Sequences of up to 900 nucleotides can be produced in a single Sanger-sequencing reaction. To determine longer sequences of nucleotides, multiple reactions are required.

DNA sequencing has been transformed by the development of next-generation sequencing technologies, which parallelize the sequencing process on a massive scale. These methods allow entire genomes to be sequenced in a time- and cost-effective manner. In “amplified single molecule” sequencing – also termed “second-generation” sequencing – DNA is fragmented into short molecules, which are amplified and then sequenced in massively paralleled reactions. Several biotechnology companies have developed second-generation sequencing platforms, each using technologies for DNA amplification and sequencing (Margulies et al. 2005; Shendure et al. 2005; Bentley et al. 2008) (see also Mardis 2008; Quail et al. 2012). An ideal platform would maximize the number of sequencing reactions per run, be able to sequence long stretches of DNA, and have a very low error rate.

More recently, “true single molecule” (third-generation) sequencing methodologies have become viable (Clarke et al. 2009; Eid et al. 2009; Thompson and Steinmann 2010). These methods can detect fluorescence at the level of individual sequencing reactions, enabling DNA molecules to be sequenced directly without the need for amplification. These reactions are able to produce DNA sequences of several thousand nucleotides, in comparison to the much shorter fragments produced by second-generation sequencing.

Luminescence Dating of Archaeological Sediments

James Feathers*

Department of Anthropology, University of Washington, Seattle, WA, USA

Definition

“Archaeological sediments” can be defined in two ways. First, it can refer to any sediment at archaeological sites even if the depositional agent is entirely geologic. A site is any locus where human activity, as identified by remains of that activity (artifacts), took place. The timing of that activity interests archaeologists. Dating sediments which contain or bracket artifacts is a proxy for dating the activity itself. Luminescence is a powerful tool for this because the event addressed is the deposition itself, assuming sunlight was sufficient to reset the signal during deposition or, if not fully, a well-bleached portion can be isolated. But luminescence is not dating the activity (Richter et al. 2009). Artifacts can be redeposited by geologic forces making their current location not where the activity occurred. To avoid misleading information, bridging arguments are required to link the event dated (last exposure to sunlight) to the activity of interest.

Secondly, “archaeological sediments” can refer to sediments who owe their deposition entirely or in part to human activity. Here the link between human activity and the dating event is direct, and bridging arguments are not required, as long as it can be shown that humans were indeed the depositional agent. The latter can be obscure if the human role is indirect, for example, when humans denude the environment of vegetation and become just a trigger for subsequent erosion.

Introduction

Luminescence dating has been applied to sediments in both cases (see earlier reviews by Roberts (1997), Feathers (2003), Jacobs and Roberts (2007)). In the former, the rationale is that the human activity cannot be dated with more precision in another way, either because the event of interest is outside the dating range of other methods, because the bridging arguments are less tenable than they are for luminescence, or because other suitable dating materials are not present. Luminescence becomes the method of choice only because other options are poorer. To be sure, the suitability of any method is not always known in advance, so many archaeologists recommend multiple methods on the premise that convergence in results lends more credibility to results because different bridging arguments are needed for each method. In the case of human-caused deposition, however, luminescence is the method of choice, because of its value as a direct dating method with no need for bridging arguments.

Where luminescence dating of sediments is a proxy for dating human activities, the contributions are largely substantive, with the only methodological (in terms of archaeology) issue related to bridging arguments. To argue that sediment dates are good proxies, the stratigraphy must have integrity with little postdepositional activity, and luminescence single-grain dating is uniquely

*Email: jimf@u.washington.edu

suited to address this issue. On the other hand, where luminescence is applied to anthropogenic sediments, the contributions are methodological (e.g., how can earthen mounds be dated?), as well as substantive.

Africa and the Middle East

Most scholars agree that anatomically modern humans originated in sub-Saharan Africa and that Middle Stone Age (MSA) lithics represent their handiwork. However, a more contentious question is when did humans become cognitively modern and how and when did they colonize the rest of the world? Dating of complex stone industries called the Howiesons Poort and the Still Bay, which appear within the MSA in South Africa, was dated with this question in mind. Prior to luminescence applications, both industries remained poorly dated. Work by Jacobs and colleagues, who applied innovative single-grain dating to several sites, culminated in an argument (Jacobs et al. 2008) that Howiesons Poort dated 60–65 ka and Still Bay around 71 ka with a significant gap between them. Conversely, Tribolo et al. (2013), using single-grain OSL along with TL dating of burned lithics at Diepkloof, produced not only older dates but suggested the durations of both industries overlap and are substantially longer, as much as 50 ka. While this disagreement is bound to foster additional research, both groups have already made an important contribution. Prior dating was so coarse-grained that the best explanatory framework was correlation with environmental change. Now OSL provides dates of sufficient precision to decouple direct changes in lithics from direct changes in climate or other environmental variables. A precise chronology of the MSA is now possible, forcing archaeologists to build explanations that consider the selective role of the environment in a more complex fashion.

North Africa and the Middle East are also involved in this issue. The question in North Africa is the age of a complex lithic industry called Aterian, often cited as evidence of modernity. Traditional dating placed the Aterian no older than 40 ka, but luminescence has pushed back the age to more than 100 ka (Jacobs et al. 2012). This has muddled the issue, because industries attributed to modern human behavior in North Africa are as old and even older than those from South Africa, and both seem to have developed independently. How modern humans got from Africa to the Middle East centers on two routes: north along the Nile into the Levant and south across the Red Sea onto the Arabian Peninsula. Luminescence has contributed to this debate in two ways: by dating sediments relevant to climate change, because the routes were hospitable to travel only at certain times (e.g., Rosenberg et al. 2011), and by dating archaeological sites themselves (e.g., Armitage et al. 2011).

Asia

How modern humans dispersed across Asia is a question with few answers because the area is vast and the number of sites investigated are few, but luminescence has been applied here as well (e.g., Petraglia et al. 2007; Haslam et al. 2011; Demeter et al. 2012; Pei et al. 2010). In East Asia, thermally transferred OSL (TT-OSL) was introduced to achieve older dates on quartz (Kim et al. 2010). Perhaps the best-known luminescence dating in Asia has been applied to sediments containing remains of the small hominin, *Homo floresiensis*, in Indonesia. Despite the lack of a fast-bleaching component, TL using red emission helped determine a 18–38 ka duration for the relict archaic hominin, well into the time of modern humans (Morwood et al. 2004).

Australia

Two issues dominate the early prehistory of Australia: When did humans first arrive and were they responsible for the extinction of the Pleistocene megafauna (Roberts et al. 2001)? Prior to the

1990s, radiocarbon had established that humans were present in Australia by about 40 ka, but the application of luminescence dating produced dates of 60 ka or older (e.g., Roberts et al. 1998b). The work is critically reviewed by O'Connell and Allen (2004), who claim little evidence for arrival earlier than 45 ka. Postdepositional mixing is the issue. Single-grain dating measures an equivalent dose or "age" for each grain and can identify mixtures of different-aged grains, if other sources of variability, including heterogeneous dose rates, can be controlled (David et al. 2007). An early application overturned previous TL dating of more than 100 ka at Jinmium rock shelter in northern Australia, by showing that a portion of grains were poorly bleached (Roberts et al. 1998a). However, at one site, Malakunanja, with OSL ages in the 50–60 ka range, single-grain dating suggested no postdepositional disturbance (Roberts et al. 1998b). Understanding the demise of the megafauna depends on whether dating the extinctions coincides with dating human arrival, and luminescence has been used to argue for and against the correlation (Roberts et al. 2001; Price et al. 2011).

Europe

Modern humans spread into Europe 40–50 ka. Exactly when they arrived and how they replaced resident Neanderthals continue to generate a large literature, and luminescence has played a key role. The Bohunician lithic tradition in south-central Europe, dated by luminescence to about 48 ka, appears to be the oldest evidence for modernity (Hoffecker 2009). Richter et al. (2009) found the most reliable dates to be TL on lithics because of poor association for radiocarbon and bad postdepositional mixing for OSL. Among the oldest hominid sites in Europe, the Atapuerca karstic complex in northern Spain has been dated by luminescence. Berger et al. (2008) used TL and IRSL on potassium feldspars to produce stratigraphically consistent dates up to 960 ± 120 ka.

North and South America

Much of the modern human debate involves times beyond the reach of radiocarbon, but not so early settlement of the Americas. However, OSL is still being applied, not only as a supplemental dating method but more importantly to provide a direct measure of sediment mixing. The issue is whether people arrived prior to the appearance of the distinctive Clovis lithic tradition that spread across North America around 13 ka. Luminescence has been applied for several pre-Clovis claims (Feathers et al. 2006; Waters et al. 2009; Lahaye et al. 2013). The Debra L. Friedkin site in Texas (Waters et al. 2011) was dated by 49 closely spaced OSL dates on quartz-dominated fine grains, which remarkably are almost all in correct stratigraphic order. The pre-Clovis artifacts are dated 15–16 ka, but an anomaly is that the Clovis layer is dated about 14 ka and the succeeding Folsom layer at 13 ka, both older than their normal age range. Lubinski et al. (2013) applied single-grain and multigrain single aliquot IRSL dating at a mammoth site in Washington. With the bones was found a piece of flake debitage in colluvium dated 16 ka. Although most of the site has stratigraphic integrity, one sample showed an intrusion of 5 ka grains, raising the possibility that the flake is also intruded.

Dating Built Structures and Human Environmental Impact Using Associated Sediments

A continual problem in archaeology is obtaining dates for prehistoric structures, whether simple rock arrangements or monumental architecture. While often the artifacts associated with these structures are reasonably well dated, the structures themselves are not.

Earthen structures are sediments deposited by humans. Any stratum within these structures can presumably be dated to the time of deposition by OSL as long as the mode of construction insured well-bleaching. Our laboratory found fill to be poorly bleached in mounds in Louisiana, but soils underneath the mounds could be dated (Bush and Feathers 2003). The rationale is that soil (or any surface exposed for some length of time) will become partially bleached by turbation processes that bring grains to the surface. Single-grain analysis using minimum age models provides age estimates for when the soil was covered over and grains could no longer reach the surface.

The same principle of dating buried surfaces has been applied to rock structures, by dating sediment below the rocks (e.g., Rink and Bartoll 2005; Outram et al. 2010). In dating soils beneath rocks in anthropogenic rock patterns in Montana and Wyoming, the author demonstrated the zeroing effect of turbation by collecting samples vertically under the rocks. Five vertical segments were dated separately, and in all samples, the youngest grains were concentrated in the segment just below the buried surface (Feathers 2012).

For rock walls, Porat et al. (2012) recommended dating sediments trapped in between rocks as these are less likely to suffer postdepositional disturbance. Work has also been done dating mortar (Goedicke 2011; Feathers et al. 2008). Superimposed sediment over rock art has been dated by OSL (e.g., Yoshida et al. 2003; Mercier et al. 2012). Susino (2010) used OSL to date microlithic debitage, isolated using an SEM, to provide a direct date for knapping activity.

Dating prehistoric canals is challenging (Huckleberry et al. 2012; Sanderson et al. 2007). The event archaeologists want to know is the construction or use of canals. Fill deposited during use may be present, although distinguishing that from post-abandonment fill is difficult. Original construction sediments may also be preserved in berms, but the berms may also contain sediments from subsequent cleanouts. Poor bleaching may be the rule, as well as bioturbation that blurs boundaries. OSL has also been used to date other agricultural features including dams and terraces (e.g., Aiuvalasit et al. 2010; Beckers et al. 2013; Avni et al. 2012; Davidovich et al. 2012).

Luminescence methods have also helped understand the impact of human activities on the environment, most work with human-induced erosion (Fuchs and Lang 2009). Several studies have also used luminescence dating to reconstruct environmental context for archaeological remains, often to show how artifact distributions might be related to site formation studies (e.g., Rhodes et al. 2010).

Issues in Application of Luminescence Dating

Postdepositional mixing is a common problem in many archaeological sediments (Bateman et al. 2007). Single-grain dating is the solution, and despite difficulties in understanding single-grain distributions, it is still preferable to multigrain aliquots where averaging masks the problem. Work in understanding the extent to which sand grains move by various agents is just the beginning but vital (e.g., Tribolo et al. 2010). Several publications report ages for Paleo-Indian sites in Brazil, not to demonstrate pre-Clovis occupations but to show stratigraphic integrity. Two showed little postdepositional sediment mixing (Araujo et al. 2008; Feathers et al. 2010), including one with a skeleton dating 12–16 ka. However, two others did show mixing of sediment grains, although chronological information could still be obtained (Araujo et al. 2013; Bueno et al. 2013). Profiling, or making minimal measurements on several small samples, is also recommended to identify badly mixed samples (Burbidge et al. 2007), something that can now be done in the field by portable luminescence readers (Sanderson and Murphy 2010). Work is also being done to understand how postdepositional mixing can affect luminescence results by studying, for example, the movement of grains by burrowing insects (e.g., Rink et al. 2013).

Partial bleaching is an important issue in luminescence dating of archaeological sediments. Detection and accurate dating of partially bleached sediments remain an issue that is not fully resolved (e.g., Murray et al. 2012).

Many archaeologists think that quartz is best for dating and know little about dating with feldspars. The recent research emphasis on dating feldspars belies the old confidence in quartz. Quartz has two major problems. First, it saturates fairly early, making it problematic for dating older sediments. This might be an underlying factor in the debate over the dating at Diepkloof, discussed earlier, because the quartz there is near saturation. Second, quartz is relatively insensitive to luminescence on about half the planet, at least with commonly used UV emission. For older sediments and in areas where quartz is insensitive, feldspar becomes advantageous, despite the disadvantage of anomalous fading. Many strides in understanding the luminescence properties of and in dating feldspars have been made in the last 5 years (e.g., Lamothe et al. 2012; Jain and Ankjærgaard 2011), particularly in the use of high-temperature stimulations. High-precision feldspar dating should be a major goal for dating archaeological sediments. In areas where even the feldspars are insensitive, more research into red TL is needed (Westaway 2009).

Conclusions

In the last decade, application of luminescence dating to archaeological sediments has increased in quantity, variety, and innovativeness. Large portions of the pre-40 ka archaeological record, particularly in Africa, are now much better known. Luminescence dating has allowed archaeologists to greatly expand their knowledge on the age of built structures. Luminescence has increased information on how humans have impacted the environment and how the environment has affected humans. It has become a major tool in site formation studies and establishing an environmental context. Single-grain dating has become a tool to investigate stratigraphic integrity and bioturbation.

Definition

H. S. Williams (1893) originally proposed the term “geochronology” for the study of the time scale of geological events. Williams coined the term just 3 years prior to the discovery of radioactivity, at a time when science-based estimates for the age of the Earth and the age of major geologic events were derived from various physical and chemical models, and a range of geologic observations and measurements. The discovery of radioactivity in 1896 by the French physicist, Henri Becquerel, led to the development of dating methods primarily based on the decay of long-lived, naturally occurring radioactive “parent isotopes” to stable “daughter isotopes.” In modern usage, “geochronology” is used more or less exclusively to refer to dating geological materials using methods based on radioactive decay.

Introduction

To quote Frank Richter’s paper on “Kelvin and the age of the Earth” (1986, p. 395): “The true vastness of geologic time, and the overthrow of the Biblical chronology that would measure it in generations of man, is in my view the most profound of geology’s many contributions.” In fact, the problem of determining the age of the Earth is also an ideal framework for a discussion of the history of geochronology. And the discussion is a lively one, replete with religious repression; battles among the titans of physics, biology, and geology; the dawn of a new scientific age with the discovery of radioactivity; and finally, the emergence of modern geochronology based on radioactive decay systems. This contribution will begin with a brief discussion of the influence of theological chronologies for the age of the Earth, followed by the gradual emergence of science-based models for the origin, nature, and age of the Earth and solar system in the face of religious persecution and, later, less lethal religious disapproval. Next is a discussion of the great scientific battles on the age of the Earth from the mid-1800s into the early 1900s that pitted leading physicists such as Lord Kelvin against the leading geologists of his day, and also against Charles Darwin and his theory of origin of the species and natural selection. Interesting subplots involve George Darwin (second son of Charles Darwin) and also John Perry (former protégé of, and assistant to Kelvin).

Then came the scientific revolution that began with the discovery of radioactivity by Henri Becquerel in 1896, revolutionizing physics and giving birth to geochronology in its modern sense. Finally, over the past 100 years or so, “modern” geochronology has developed and matured into an essential field for the study of Earth, moon, and solar system origin and history.

Age of the Earth from Religious Sources

Many ancient civilizations developed creation stories, some including specific ideas about time. The ancient Greeks, Hindus, Chaldeans, and Mayans believed in infinite time, usually in the form of repeated cycles, each one lasting millions of years. The longest cycle in the Mayan “long count” calendar lasted ca. 6.3×10^7 year. However, far more important in the western world over the past 2,000 years or so were numerous calculations for the date of creation of the Earth and humans, using as a starting point Biblical sources such as the Book of Genesis. Beginning in about 169 A.D., church scholars calculated a series of very young ages for the Earth ranging from ca. 6,000 to 9,000 years BP.

James Ussher (1581–1656), an Archbishop in the Irish Anglican Church, published the most influential “age of the Earth” in the 1650s. Ussher’s date of October 22, 4004 B.C. for the creation of the Earth was not the first ca. 4000 B.C. calculation, but it was inserted as a marginal note into the 1701 edition of the English Bible, some 45 years after Ussher’s death. Insertion into the Bible, even as a marginal note, gave the 4004 B.C. date all the weight of inerrant Biblical truth to those who believed in a literal, word for word interpretation of the Bible. This had a profound impact on the emergence of scientific inquiry. Long before Ussher’s date was embedded in the Bible, holding, teaching, and/or publishing views that conflicted in any way with church dogma could lead to charges of heresy. However, the threat of persecution fluctuated, depending whether the Roman Catholic Church had more serious issues to deal with at any given time. For example, Copernicus (1473–1543) published his book on the heliocentric theory of the solar system in 1543. He actually dedicated the book to the sitting Pope, even though the heliocentric model was obviously in direct conflict with the geocentric solar system/universe of Genesis. However, at the time, the Roman Catholic Church had other, more pressing issues to deal with.

The “Protestant Reformation” of Martin Luther began in ca. 1517 with the printing and posting of Luther’s “disputations.” The movement spread rapidly, and grew into a more and more serious threat to the Roman Catholic Church. In the 1530s, Henry VIII implemented the “English Reformation” and also broke away from the Roman Catholic Church. Little wonder then that Copernican theory was a relatively low priority for Church investigation. As a result, the work of Copernicus, and those who supported his work, such as Galileo, escaped formal condemnation for many decades. By ca. 1545, only 2 years after the death of Copernicus, the Catholic Church began a formal “Counter Reformation.” However, when reformation movements continued to grow, even spreading into Italy, the Roman Catholic Church took a more extreme step, instituting a new inquisition, the “Roman Inquisition,” in 1588. In the early years of the inquisition, heliocentrism was still not the highest priority, but in 1616 the Church finally got around to Copernicus (73 years after his death!) formally denouncing the heliocentric model of Copernicus as “dangerous to faith” and banning his book.

At the time of the denunciation and ban, Galileo already had been publishing material in support of Copernicus for several years, based in part on his own telescopic observations. Galileo was

required to appear before a powerful Cardinal who ordered him not to “hold or defend” Copernican theory. Presumably, Galileo complied with this order for several years. However, in 1623, an old friend of Galileo’s became Pope Urban VIII, and Galileo was emboldened to publish about Copernican theory in a way that he thought might not directly violate the Cardinal’s orders. In 1632, Galileo published a book on Copernican theory, thinly disguised as a conversation between fictional characters, one arguing for, and the other against Copernican theory. One character, “Salviati” (obviously Galileo), brilliantly presented evidence supporting Copernican theory, including detailed astronomical observations, graphs, etc. The other character, the unfortunately named “Simplicio” (representing the Church, perhaps even the Pope himself), comes across as dim-witted, befuddled by Salviati’s arguments, and able only to present the standard church position in opposition to Copernican theory. The one-sided nature of the “debate” was all too obvious. Galileo was examined by the inquisition, found guilty, forced to recant, his book was banned, and he was placed under house arrest for the rest of his life. It took just over 200 years for Galileo’s book to be removed from the banned book list. Little wonder then, that for many years, most observers of the natural world carefully fitted their interpretations into the time frame of Archbishop Ussher, either from true belief or self-preservation. To quote Burchfield (1990, p. 5): “The question to be answered by the natural philosopher was not how long it had taken for geological forces to sculpture the face of the Earth, but how they had accomplished their work in the few millennia since Creation.”

Age of the Earth from Early Scientific Methods: Pre-Kelvin

Eventually, scientists began to push more openly against the constraints placed on them by an Earth only several thousand years old. As the science of geology began to emerge, in particular, the study of processes such as uplift, erosion, and sedimentation, the concept of a far more ancient Earth began to emerge. Initially, caution was still required. For example, Benoit de Maillet (1656–1738), French diplomat and naturalist, traveled widely as a diplomat and made many observations of geology and geography around the Mediterranean. He concluded that the Earth must be greatly older than the Ussher Biblical chronology suggested, perhaps on the order of 2 Ga. He presented his theory, based on a theory of steady gradual lowering of sea level over geologic time, in the form of fictional conversations between a French missionary and an Indian sage named “Telliamed” (de Maillet spelled backward). Having been born only 14 years after the death of Galileo, de Maillet would have been well aware of Galileo’s persecution, so he took the additional precaution of arranging for his own book to be published in 1748, 10 years after his own death.

One of the most remarkable scientific figures of the eighteenth century was Georges-Louis Leclerc (1707–1788), later the “compte de Buffon,” courtesy of King Louis XV of France. In 1749, just 1 year after the posthumous publication of de Maillet’s theory, Buffon published the first 3 of his 35 volumes on “Natural History...” Buffon, who would become one of the giants of the Enlightenment, proposed a detailed theory for the origin of the planets that was clearly at odds with Genesis. However, he claimed that his theory was only “pure philosophical speculation.” This, plus the fact that Buffon had the strong support and protection of Louis XV, saved him from any serious action by the Church. Of even more interest from the perspective of geochronology are the scientific experiments Buffon conducted to provide some actual numerical estimates of the age

of the Earth. In addition to his many other talents and enterprises, Buffon owned an iron foundry. On the theory that the Earth had cooled from an originally molten state, Buffon had his workers make a series of spheres of graduated sizes, some of pure iron, others mixtures of iron and silicates. He had the spheres heated to just below the melting point, then measured the time required for the surface of each sphere to cool to the point where it could be touched with a bare hand without burning the fingers, then the time for the surface to reach room temperature. From these data, Buffon extrapolated how long it would take for a sphere the size of the Earth to cool. The “short version” of the results, published in 1778, gave a result of 75 Ka for the Earth to cool to its present temperature. “Long chronologies” found in Buffon’s unpublished manuscripts give results as high as 3 Ma. Why the large discrepancy? “Internal evidence strongly suggests that Buffon favored the longer version. Why, then, did he elect to publish the shorter? . . . The best guess is that he thought the lower figure was about as much as the traffic would bear.” (Albritton 1980, pp. 85–86).

With the emergence of “the Enlightenment,” and especially in non-Catholic countries, it became more acceptable to challenge the Biblical chronologies. For example, James Hutton (1726–1797) published a paper in 1785 that would revolutionize geologic thinking. Hutton’s studies convinced him that ordinary geologic processes acting over vast amounts of time could explain all of his observations. Hutton saw no need for great Biblical catastrophes, such as Noah’s flood. Working in Scotland, Hutton did not have to fear an inquisition, but religious beliefs were still strongly held by many. To paraphrase one of Hutton’s most caustic critics: “. . . the suspicion of the high antiquity of the globe has been fatal to Mosaic (i.e., Biblical) history, and consequently to religion and morality” (see Burchfield 1990, p. 7, emphasis added). Charles Lyell (1797–1875) published his *Principles of Geology* in 1830, reinforcing and popularizing Hutton’s concept of gradual changes over “inconceivably vast” periods of time. Charles Darwin (1809–1882), a contemporary, friend, and admirer of Lyell, published *On the Origin of Species* in 1859, depending heavily on the availability of great expanses of time for the operation of natural selection.

Age of the Earth from Early Scientific Methods: The Kelvin Era

The writings of Hutton, Lyell, and, in particular, *On the Origin of Species* by Darwin served as a major catalyst for a great flowering of inventive approaches for estimating the age of the Earth (or the oceans, or the sun, or the moon, or the Earth “as an abode fitted for life”) from the mid-1800s to the early 1900s. Scientists applied physics, chemistry, and geology to the “age of the Earth problem.” The age estimates based on a wide range of approaches varied over orders of magnitude and sparked several decades of heated and sometimes bitter controversy. The central figure was William Thomson (1824–1907), later known as Lord Kelvin, courtesy of Queen Victoria’s 1892 elevation of Thomson to a “peer of the realm.”

Kelvin was widely regarded as the most brilliant physicist of his era by his peers. Kelvin evidently strongly agreed with this opinion, and he was particularly resistant to changing any of his ideas, even in the face of new information, which he did not always keep up with anyway: “Kelvin’s failure to keep up with the literature even in his own field was notorious. It led him frequently to repeat experiments and discoveries already in the literature” (Burchfield 1990, p. 54). As with many other scientists of his era, Kelvin had broad interests, including geology, but geology’s lack of quantitative rigor annoyed him. He particularly objected to “uniformitarianism,” as proposed by Hutton and expanded by Lyell. The idea of terrestrial conditions such as surface temperatures remaining largely the same over unimaginably long periods of Earth history was

anathema to Kelvin. After all, Kelvin had discovered the second law of thermodynamics. The Earth had to be cooling, with a consequent slowing down of geologic processes over time. Kelvin was also annoyed by Charles Darwin's demands for vast lengths of time for the process of natural selection. Starting in ca. 1862, and extending for over the 40 or so years, Kelvin fought a running battle with geologists, biologists, and even fellow physicists. Starting in the 1860s, Kelvin published a series of papers on the age and energy source of the sun, the age and thermal history of the Earth, and the effects of tidal friction retarding the rate of rotation of the Earth. All of these studies were designed to place quantitative limits on the age of the Earth as a planet, or "the age of the Earth as an abode fitted for life."

Kelvin's work on the thermal history of the Earth is perhaps the best known. His approach was similar to that of Buffon, except that Kelvin used data from the Earth itself, rather than from experiments on small spheres. Kelvin assumed that the Earth initially was totally molten, solidified completely from the core outward, then cooled entirely by conduction to its present thermal state. He used measured thermal gradients from wells and mines, measured thermal conductivities for a few common crustal rock types (and assumed that these conductivities applied to the entire interior of the Earth), and then applied the mathematical approach to heat transfer published by Fourier in 1822. Kelvin derived an "age" for the Earth (at least, the time since the outermost crust solidified) of 98 Ma, but allowed a range of 20–400 Ma, based on uncertainties of his data. The ca. 100 Ma figure published by Kelvin in 1862 is widely quoted, but over the following decades, Kelvin reduced both his estimate for the Earth's age, and the uncertainties. To quote Burchfield (1990, p. 43):

By 1868 he was convinced that sufficient evidence existed to justify limiting the assumed duration of life on Earth, if not the Earth's total age, to no more than 100 million years. In 1876, he was willing to accept an upper limit of only 50 million years for the Earth's age, and in 1881 a limit of 20 to 50 million years. Finally, in 1897, he declared that the Earth's age was nearer 20 million than 40 million years, and embraced Clarence King's estimate of 24 million years as the best available.

Also in 1862, Kelvin published estimated age limits of 10–500 Ma for the sun – quite similar to his original limits for the age of the Earth of 20–400 Ma. Kelvin ruled out chemical reactions as a source of energy for the sun and proposed that the sun's heat had been produced primarily by gravitational accretion during its formation. Thus, he viewed the sun, like the Earth, as a simple cooling body with no internal source of energy. As Kelvin's estimates for the age of the Earth came down, he eagerly accepted younger estimates of the sun's age published by some of his colleagues. As the assumptions of his original work on the age of the Earth came under attack, he relied more heavily on these estimates of the sun's age to cling to his original conclusions about the Earth.

One of the more fascinating approaches by Kelvin was based on retardation of the Earth's rotation by oceanic tidal friction and the implications for the Earth's equatorial bulge. Kelvin pointed out that a totally molten Earth would assume a polar flattening and equatorial bulge in proportion to its rate of rotation. Kelvin then assumed that when the Earth completely solidified, it would become many times more rigid than steel and could no longer respond to changes in the rate of rotation. Thus, Kelvin reasoned, the equatorial bulge would be locked in at the time of solidification. By knowing the rate of slowing of the Earth's rotation, one could theoretically calculate when, in the past, the rate of rotation matched the supposedly locked in (present) shape of the Earth. In fact, the present shape of the Earth is consistent with its present rate of rotation. Kelvin, recognizing that there were great uncertainties in his approach, concluded that the data could only limit the age of the Earth's solidification to <1 Ga. What he failed to recognize (or chose to ignore) was that a "young" Earth was not the only explanation for the agreement between the present shape of the Earth and the present rate of rotation. The data were also consistent with the

present-day Earth being nonrigid – capable of flowage and continuously adapting its shape to the slowing rotation rate of the Earth.

One of the interesting “subplots” in the “age of the Earth” debate was the involvement of George Darwin, the second son of Charles Darwin. George Darwin, an eminent and respected scientist in his own right, was a professor of “astronomy and experimental philosophy” at Cambridge for almost 30 years. Early in his career, he had attracted the attention of Kelvin, who responded enthusiastically to George’s first major paper on the effects of geological change on the Earth’s rotation. Kelvin encouraged George to analyze the tidal interactions of the Earth-moon system, to follow up Kelvin’s Earth-ocean tide study. The work led to George’s well-known 1879 theory that the moon had spun off from the Earth during an earlier era of more rapid rotation. The calculations also gave a *minimum* age of 54–57 Ma for the Earth/moon system to reach the present Earth/moon axial rotation rate/orbital period, but Darwin pointed out that the *maximum* age might be very much greater. As might be expected, Darwin’s theory of lunar origin sparked considerable interest by both the scientific community and the general public. Unfortunately, popular versions tended to be oversimplified: “Thus too little emphasis was given to the fact that the figures 54 million and 57 million years for the moon represented possible minima and in no way limited the maximum age of the Earth-moon system. Instead these figures passed into the literature as still another proof that the Earth *must* be less than 100 million years old” (Burchfield 1990, p. 115). It is interesting that George Darwin’s calculations were all based on a viscous, nonrigid Earth. This stands in sharp contrast to Kelvin who based both his cooling and tidal models on a completely rigid Earth. Instead, Darwin’s model of a viscous Earth was in accord with geological data that were being used at about the same time to attack Kelvin’s age(s) for the Earth.

General references: Albritton (1980), Burchfield (1990), Dalrymple (1991), Holmes (1913).

Age of the Earth from Early Scientific Methods: The Geologists Fight Back

Some geologists (and a few physicists) began attacking Kelvin’s assumptions. No one was willing to challenge Kelvin’s prowess as a mathematician, but many believed that Kelvin’s assumption of a rigid Earth, physically uniform throughout, was the Achilles heel of his model. For example, the Reverend Osmond Fisher (1817–1914), an early geophysicist from the long and rich tradition of theologically trained naturalists, mounted an attack against Kelvin. In “Physics of the Earth’s Crust,” published in 1881, Fisher summarized evidence for depression of the Earth’s crust in Scandinavia by glacial ice-loading and post-glacial rebound of the crust after the glaciers had melted. It was obvious to Fisher that the geological evidence was completely incompatible with Kelvin’s rigid Earth assumption, instead requiring the crust to float on a viscous interior. Fisher continued his attacks in a series of papers with titles such as “On depression of ice-loaded lands,” published in 1882, and “Rigidity not to be relied on in estimating the Earth’s age,” published in 1893.

Even more telling were the analyses of John Perry (1850–1920). Perry was a brilliant mathematician and also a former student, assistant, and collaborator of Kelvin’s. Perry was obviously fond of Kelvin and thus was reluctant to criticize Kelvin’s work on the age of the Earth, making this another interesting “subplot” in the controversy over age of the Earth: “Some of my friends have blamed me severely for not publishing the above document sooner. I was Lord Kelvin’s pupil, and am still his affectionate pupil. . . . He has been uniformly kind to me, and there have been times when he must have found this difficult” (Perry 1895). Affection and respect notwithstanding, Perry was particularly concerned with Kelvin’s simplistic assumptions that the Earth’s physical

properties, including thermal conductivity, were uniform throughout and that the Earth was rigid, with no possibility for convection. Suppose “quasi-conductivity” (conduction plus some convection) allowed the transfer of heat from the Earth’s interior to the base of the crust at ten times the rate based on Kelvin’s measurements of conductivity of typical upper crustal rocks? Perry (1895) demonstrated that such an increase in heat transfer from the Earth’s deep interior would increase Kelvin’s calculated age for the Earth by a factor of 56. Perry’s goal was not to calculate a specific age for the Earth but to show that Kelvin greatly underestimated his *upper limit* for the age of the Earth. Perry (1895, p. 227) includes a letter from Kelvin, in which Kelvin more or less concedes this point: “. . . I thought my range from 20 millions to 400 millions was probably wide enough, but it is quite possible that I should have put the superior limit a good deal higher, perhaps 4000 instead of 400. . . .” However, Kelvin quickly reverted to much younger age limits. Even after the discovery of radioactivity, the production of heat from radioactive decay, and publications of the first dates based on radioactive decay, Kelvin clung tenaciously to his earlier ideas.

Meanwhile, geologists had devised methods of their own to calculate the age of the Earth. Particularly popular were methods based on observed thicknesses of sedimentary rock coupled with estimated rates of erosion and sedimentation and methods based on ocean chemistry, predominantly those based on sodium accumulation. Excellent, detailed, and very readable accounts have been provided by Albritton (1980), Burchfield (1990), and Dalrymple (1991) and are very briefly noted here. Between 1860 and 1917, some 32 papers by 21 different authors estimated the ages of various parts of the sedimentary record, based on erosion and sedimentation rates (Dalrymple 1991, Table 2.1). Results varied wildly from ca. 3 Ma to ca. 15 Ga, but some efforts were remarkably accurate. For example, John Goodchild in 1897 published a detailed analysis of the Phanerozoic sedimentary record. To quote Burchfield (1990, p. 148): “Goodchild’s approach was eclectic. Borrowing freely from the methods pioneered by Phillips, Reade, Geike, and others, he determined the duration of each separate geological period using what he regarded as the most appropriate and reliable method for each. . . . In all, he determined the ages of 15 geological periods since the beginning of the Cambrian, totaling just over 700 million years. . . .” This is a stunning result, considering that our present age for the beginning of the Cambrian is just over 540 Ma, less than 25 % below Goodchild’s figure. Goodchild also estimated “at least an equal duration for the Precambrian” for an age of the Earth >1.4 Ga. However, a significant number of the other estimates based on sedimentation and erosion did fall within Kelvin’s original 20–400 Ma age limits.

Between 1876 and 1931, some 12 papers by nine different authors used the chemistry of the oceans to place limits on the age of the Earth (Dalrymple 1991, Table 2.1). Most of the studies used methods based on sodium in the oceans. Perhaps the best-known results and those most widely quoted in elementary texts were by John Joly (1857–1933). In 1899, Joly proposed a simple model: (1) that the primordial oceans were freshwater, condensed from the Earth’s atmosphere when surface temperatures dropped below the boiling point of water soon after the Earth’s crust solidified, and (2) that over the remainder of the Earth’s history, the oceans gradually became more and more salty by the addition of sodium weathered from the continents and carried into the ocean by rivers. The concentration of Na in the oceans was already well known, the volume of the oceans had been estimated, and the Na contents and discharge rates of most major rivers were approximately known. Joly had only to divide the total Na in the oceans by the annual Na flux of the rivers to estimate the age of the oceans, and the time elapsed since the Earth had cooled below the boiling point of water. Applying a few corrections and allowing for uncertainties in the data, Joly calculated that the oceans had an age between 80 and 90 Ma. In 1900, Joly adjusted his estimate slightly upward, to 90–100 Ma. Comparable calculations by other authors using slightly different

inputs arrived at more or less identical results – ca. 100 Ma. Again, these estimates were in agreement with Kelvin’s original age estimates for the Earth and sun. Some geologists were ready to accept an age for the Earth of ca. 100 Ma and do their best to fit all of Earth history into this “modest” time frame. However, Kelvin, Tate, King, and others kept reducing their estimates (still based on calculations of heat loss), limiting the age of the Earth and sun to only 10–40 Ma. As mentioned earlier, Kelvin’s final word on the subject in 1897 was that Clarence King’s 24 Ma age for the Earth, published in 1893, was the best available.

However, the scientific world was about to change dramatically. In the few years encompassing Perry’s 1895 critique of Kelvin’s assumptions, Goodchild’s 1897 estimate of the age of the Phanerozoic, Kelvin’s 1897 “final word,” and Joly’s 1899 age of the oceans, a spectacular scientific revolution was beginning. The discovery of x-rays by Roentgen in 1895 led directly to the discovery of radioactivity by Becquerel in 1896 which led, within a decade, to direct measurements of ages on minerals and rocks based on radioactive decay systems. Modern geochronology had been conceived.

General references: Albritton (1980), Burchfield (1990), Dalrymple (1991), Holmes (1913).

The Discovery of Radioactivity and the Birth of Geochronology

In the late 1800s there was a general impression in physics that all the great discoveries had been made. Younger physicists would have to be content with improving the accuracy and precision of already known physical constants. Then, late in 1895, only months after Perry had published his critique of Kelvin (and exposed the fatal flaw in Kelvin’s assumption about the Earth’s transfer of heat), Wilhelm Roentgen (1845–1923) discovered “X-rays,” penetrating rays emitted from a cathode ray tube. X-rays became an overnight sensation – “radiographs” showing the bones inside the hand of a live human being must have seemed absolutely magical; the general public was enthralled. The scientific community also was invigorated by this completely unexpected development. Well, most of the scientific community: “Kelvin was not moved. He had regarded the original announcement of Roentgen’s x-rays as a hoax” (Albritton 1980, p. 204). To be fair, an 1896 X-ray image of Kelvin’s own hand exists, so he soon accepted Roentgen’s discovery. One of the many scientists who did pay close attention to Roentgen’s discovery was physicist Henri Becquerel (1852–1908). To quote from a summary by Mattinson (2013a, p. 2):

Following in his father’s footsteps, Becquerel had conducted research in phosphorescence, the property of some materials, including some uranium compounds, to emit light after exposure to sunlight or ultraviolet light. However, by 1895, the 43-year-old Becquerel evidently had been inactive in research for about five years. The discovery in late 1895 by Wilhelm Roentgen of ‘X rays’ emitted from a cathode-ray apparatus spurred Becquerel back into action. Becquerel began experiments on some of his phosphorescent uranium samples to determine if they might emit not just visible light, but also invisible penetrating rays similar to Roentgen’s X-rays.

Becquerel placed photographic plates that he had wrapped in heavy black cloth on a south-facing windowsill and placed uranium samples on top of the covered photographic plates. After exposure of the uranium samples to sunlight, Becquerel developed the plates to see if any rays from the uranium had penetrated the black paper and exposed the plate. Fortune smiled on Becquerel. First, some of his previous phosphorescence work had been on uranium compounds. Of all the elements, only uranium and thorium and radioactive “daughter” elements produced by their decay generate strong penetrating radiation. If Becquerel had not had U or Th samples available, all his results would have been negative. Instead, he almost immediately obtained positive results – the plates had been exposed, producing fuzzy images the shape of the samples placed on the plates. Second,

Becquerel initially assumed that activation by exposure to sunlight was necessary for any penetrating rays to be produced, by analogy with true phosphorescence. However, for reasons that have never been clear (e.g., Badash 1996), after a period of dark, rainy weather, Becquerel developed some photographic plates, even though the uranium samples had *not* been exposed to sunlight – they had been left in a closed drawer, on top of the covered photographic plates. The photographic plates showed the same degree of exposure as before. Becquerel realized that the exposure was not related to activation by sunlight, but was an inherent property of the uranium samples. The new form of radiation, initially referred to variously as “uranium-rays” or “Becquerel-rays,” was later called “radioactivity” by Marie and Pierre Curie. That name would stick.

Initially, Becquerel’s discovery was greatly overshadowed by Roentgen’s discovery of X-rays. It was not immediately apparent that Becquerel had discovered an entirely different phenomenon, and scientists were slow to enter the new field of radioactivity. Quinn (1995, p. 143) in her excellent book on Marie Curie comments:

Becquerel himself seems to have concluded that the subject was exhausted: after his initial papers in 1896, he published only two in 1897 and none the following year. By early 1898, as science historian Lawrence Badash has noted, the subject was ‘something of a dead horse.’ Other than Becquerel’s papers, only four were devoted to the uranium rays at the Academy in the year of their discovery. In contrast, Gustave LeBon’s false claims for ‘black light’ were the subject of fourteen papers. And Roentgen’s X rays got the most attention of all. Nearly one hundred papers were delivered at the Academy in 1896 concerning X rays.

In this respect it seems particularly ironic that one of the very few scientists who took any interest in confirming some of Becquerel’s work was William Thomson (Lord Kelvin), then 73 years old. The general lack of interest in Becquerel’s discovery (certainly) and the fact that Kelvin, who did show interest, had, for the previous few years been somewhat of a mentor to Pierre Curie (likely) were responsible for Marie Curie choosing to study radioactivity for her Ph.D. project, starting in 1898. Marie soon found that the mineral pitchblende (uranium oxide) was several times more radioactive than pure uranium metal. This led her to discover two new radioactive elements, radium (Ra) and polonium (Po), both decay products of uranium. She then concentrated Ra for chemical characterization and further study. Marie’s meticulous work and exciting discoveries inspired others to enter the field:

In a series of brilliant papers in 1902, Ernest Rutherford and Frederick Soddy established that radioactivity resulted from the transformation of unstable elements into new forms. A competing theory, that radioactive elements were somehow absorbing then releasing energy from outside sources, soon died out. Rutherford and Soddy derived the mathematical principles of radioactive decay and suggested that helium (He) was a stable daughter product of U decay. Rutherford realized that the ratio He/U could be used to measure the ages of geological materials and presented the first dates based on radioactive decay in a 1904 lecture. (Mattinson 2013b, p. 53)

Modern geochronology was born.

Meanwhile, in 1903, Pierre Curie and Albert Laborde discovered that the radioactive decay of Ra produced enormous amounts of heat, invalidating Kelvin’s assumption of a simple cooling Earth with no internal heat source (more on this later). The discovery inspired a flurry of letters to *Nature* in 1903. W. E. Wilson, an independent “gentleman-astronomer” (Letter to the Editor, July 9, 1903) enthusiastically suggested that if the sun contained 3.6 g of radium per cubic meter, its entire energy output could be provided by the radioactive decay of radium (later, Joly and Rutherford would point out that to support this concentration of radium, the sun would have to be made up almost entirely of uranium!). George Darwin was more nuanced in a September 16, 1903, letter: “Knowing as we now do, that an atom of matter is capable of containing an enormous store of energy in itself, I think we have no right to assume that the sun is incapable of liberating

atomic energy to a degree at least comparable with that which it would do if made of radium.” John Joly also weighed in, commenting on the effects of heat from radioactive decay in the sun and the Earth in an October 1, 1903, letter: “. . . it would appear that the estimates derived from physical speculations are now subject to modification in just the direction which geological data required. The 100 million years which the doctrine of uniformity requires may, in fact, yet be gladly accepted by the physicist.” Note: Joly’s enthusiasm for methods based on radioactive decay dimmed when the first He/U and Pb/U dates indicated that Joly’s own method greatly underestimated the age of the Earth.

The year 1903 was also the year that the Nobel Prize in physics was awarded jointly to Henri Becquerel, Pierre Curie, and Marie Curie for their work on radioactivity. Radium, radiation, and the Curies quickly acquired superstar status. In the geological community, the enthusiasm for radium, along the lines of the *Nature* letters quoted above, promoted a myopic focus on radiogenic heat production as dealing the fatal blow to Kelvin’s four-decade dominance of the age of the Earth debate. This view is still promoted in many elementary texts, e.g., “Perhaps the most durable myth in elementary Earth science texts is the view that the discovery of radioactivity . . . and radioactive heat generation . . . forever ended the late nineteenth century controversy involving Lord Kelvin and the age of the Earth” (Harrison 1987). A most unfortunate side effect was that John Perry’s devastating (and much more correct) 1895 critique of Kelvin’s model sank into obscurity and remained there until relatively recently. A modern analysis of Kelvin’s approach to the age of the Earth demonstrates that Perry had it right:

. . . even if Kelvin had included a reasonable radiogenic heat production in his thermal evolution models, he would still have found grounds for arguing that the age of the Earth was on the order of 10^8 years. The essential missing process *is not really radiogenic heating at all but thermal convection*, which allows the surface flux to exploit the entire heat of the Earth as opposed to simply that of a shallow conductive boundary layer. (Richter 1986, p. 397, emphasis added)

But Richter inexplicably makes no reference to Perry, even though Perry’s contributions are thoroughly covered in the 1975 first edition of Burchfield’s book, which Richter cites as a general reference for the age of the Earth controversy. This oversight was pointed out by Harrison (1987) and corrected in later papers by Richter and his colleagues. “If the scientific community of the day had absorbed Perry’s message. . . The realization that convection takes place within the Earth’s apparently solid interior would have made it hard to sustain the “fixist” view of the Earth—which held that it was physically impossible for continents to move horizontally. That perception of fixity exerted a powerful brake on geological progress in the first half of the 20th century. . .” (England et al. 2007, p. 349).

Within a few years of the paper on radium heat production by Curie and Laborde and the Nobel Prize for Becquerel and the Curies, the first dates of geologic materials based the decay of uranium to helium were formally published by Rutherford in 1906 and those based on the decay of uranium to lead (the ultimate stable end-product of the uranium “decay series”) were published by Bertrand Boltwood in 1907, demonstrating that Paleozoic and Precambrian rocks ranged from hundreds of millions to billions of years old. Lord Kelvin died in 1907, but not before reasserting his belief that gravity was the only possible source of the heat of the Earth and sun, and suggesting “. . . that somehow ethereal waves may supply the energy to the radium as it is giving out heat to the ponderable matter around it” (Burchfield 1990, p. 165). This was a version of an idea held for a time by Becquerel and the Curies, the phosphorescence model, that the energy released by radioactive decay had somehow been absorbed from outside forces. With Kelvin’s death, one might have imagined that the geological community would have embraced the new field of geochronology with great enthusiasm. This would be a mistake. First, radioactivity had been discovered and

studied by physicists and chemists, who also presented the first dates based on radioactive decay. Having been burned once by the physicists (Kelvin et al.), geologists were wary:

Radioactive dating clearly had not taken geology by storm. As Joseph Barrell succinctly summarized the situation in 1917: ‘After one experience with the fallibility of physical argument notwithstanding its mathematical character, it would certainly be unwise for geologists to accept unreservedly the new and larger measurements of time given by radioactivity. There may be here, also, factors undetected and unsuspected which vitiate the results’. (Burchfield 1990, p. 190)

Second, some geologists had a considerable intellectual investment in their own earlier estimates of the age of the Earth. For example, Joly’s 100 Ma age based on the salinity of the oceans had gained him considerable attention and prestige, especially after heat from radioactive decay seemed to invalidate Kelvin’s most recent younger estimates of the age of the Earth. Only a couple of years later, ages based on radioactive decay published by Rutherford and Boltwood appeared to demolish Joly’s 100 Ma figure. Joly denied the validity of radiometric ages for more than two decades. “It was not until 1930 that he showed any sign of actually yielding to the accumulated mass of radiological evidence, and like Kelvin he died without publicly relinquishing his convictions” (Burchfield 1990, p. 189). By then, Rutherford and Boltwood had long since left the field of geochronology, having returned to their main interests in the physics of matter and radioactive decay, and the chemistry of the U and Th decay series, and new giant in the field of geochronology had emerged – Arthur Holmes.

General references: Albritton (1980), Badash (1996), Burchfield (1990), Dalrymple (1991), Holmes (1913), Quinn (1995), Rhodes (1986).

Arthur Holmes and the Growth of Geochronology

Arthur Holmes (1890–1965) was a small boy when radioactivity was discovered, and a teenager when the first He/U and Pb/U dates were published. He grew up with the excitement of the dawning of a new scientific era. Holmes attended a “higher grade school” with a strong science orientation, and an exceptional physics teacher who used geological examples in many of his lectures. In 1906 Holmes was mesmerized by an exchange of letters in *The Times of London*. Kelvin initiated the exchange after he read a report in *The Times* about new experiments on radioactivity by Soddy and William Ramsay:

Kelvin wrote an angry letter to *The Times* criticizing their work. . . .he also considered it added nothing new to the theory of atoms that had been proposed by Democritus two and a half thousand years ago! The irritation felt by the younger generation by Kelvin’s obstinate refusal to accept the new evidence was thinly veiled: ‘Lord Kelvin’s letter will of course receive respectful attention. . .but it is also known that his brilliant original mind has not submitted patiently to the task of assimilating the work of others by the process of reading’. (Quinn 1995, pp. 11–12)

The bare-knuckles match went on for over a month, with Kelvin on one side, and the young lions of radioactivity on the other: Ramsay, Rutherford, Soddy, and Robert Strutt (the latter having narrowly missed becoming the first to publish an age based on the accumulation of helium from U decay). Holmes was hooked!

In 1907 Holmes started to study physics at the Royal College of Science, London. In his second year, Holmes renewed his interest in geology thanks to a brilliant and dynamic young geology professor, William Watts. After Holmes’ second year, he switched his emphasis to geology. Another young professor at the Royal College of Science was none other than Robert Strutt. Holmes recognized a splendid opportunity to combine his interests in geology and radioactivity

and began a research project developing improved Pb/U dating techniques under the direction of Strutt. The timing was particularly fortuitous, as Boltwood had returned to his primary research interest on the chemistry of the uranium and thorium decay series, leaving the newly born field of Pb/U geochronology wide open. Almost immediately, Holmes made a series of important contributions. He developed more sensitive chemical and radiochemical techniques for the measurement of U and Pb than those used by Boltwood. Whereas Boltwood had been limited to U-rich ore minerals, Holmes could analyze minerals much lower in U and Pb such as zircon and even feldspar. Using an updated decay constant for U, Holmes published a series of new Pb/U analyses and dates and also recalculated Boltwood's earlier Pb/U dates. Arthur Holmes, the physicist, might have stopped there, but Arthur Holmes, the geologist, investigated the geological settings of all the samples dated and produced the beginnings of a geologic time scale in 1911. Holmes' results are remarkable in that they are all in general agreement with modern results: Carboniferous ca. 340 Ma, Devonian ca. 370 Ma, "pre-Carboniferous" ca. 410 Ma, "Silurian or Ordovician" ca. 430 Ma, and Precambrian ca. 1,025–1,640 Ma. Holmes published a 196 p. monograph in 1913 boldly titled "The Age of the Earth." The book provides a summary of early efforts to determine the age of the Earth and gives a flavor of the commonly bitter controversies that surrounded these efforts. As discussed above, some of the same geologists who considered Lord Kelvin's estimates of the age of the Earth to be much too young now objected to minimum ages for the Earth based on radioactive decay systems as being much too old. Holmes hoped to use his book to convince the geological community of the fundamental accuracy of geochronology based on radioactive decay. Summarizing all the available He/U and Pb/U dates, Holmes presented an expanded version of his geologic time scale, from Pleistocene to Precambrian. For Holmes, this was only the beginning of a long and remarkable career devoted to expanding and improving the dating of the geologic time scale and determining the age of the Earth itself.

The Discovery of Isotopes and Early Isotopic Research

As might be expected, the discoveries of x-rays, radioactivity, and the radioactive transmutation of atoms into different forms had far-reaching effects, inspiring a great outburst of research on the nature of matter itself. In 1911 Rutherford discovered the atomic nucleus by bombarding thin metal foils with collimated beams of alpha particles. Highly accurate measurements revealed that the atomic weights of many elements were not whole numbers. In particular, in 1913, T. W. Richards measured the atomic weight of Pb produced by the decay of U and found that it was significantly lower than the atomic weight of "ordinary" Pb. Innovative instrumentation played an increasingly vital role. J. J. Thomson (Rutherford's professor) built a "positive ray" apparatus, a simple antecedent to today's mass spectrometers. Thomson discovered that neon had two different forms – one with a mass of about 20 and another with a mass of about 22. Soddy coined the term "isotopes" for these atoms of the same element but with different atomic masses. The neutron was suggested by Rutherford in 1920 (later confirmed experimentally by Chadwick in 1932), fleshing out the basic picture of the atomic nucleus. In 1920, F. W. Aston built an advanced version of Thomson's "positive ray" instrument. Aston's "mass spectrograph" used photographic plates to record the mass spectra of elements and allowed semiquantitative measurements of isotopic ratios. After confirming Thomson's work on neon, Aston went on to investigate the isotopic composition of many elements over his career, including "ordinary" Pb from Pb ore samples in 1927 and

“radiogenic” Pb from a U ore sample in 1929. Pb from the U ore unexpectedly contained ^{207}Pb . This discovery led to the inference that U contained not just ^{238}U , but also a minor, previously unknown isotope that was the parent of ^{207}Pb , i.e., ^{235}U . J. L. Rose and R. K. Stranathan in 1936 realized that the different decay rates for ^{238}U and ^{235}U required that the $^{207}\text{Pb}/^{206}\text{Pb}$ ratio of Pb produced by uranium decay increase with increasing age – an age could be determined for a uranium-bearing mineral simply from the lead isotopic composition alone. Thus the foundation for modern isotope geology and geochronology was laid.

Alfred Nier, Isotopes, and Mass Spectrometry

Over the next several years, improvements in instrument design resulted in the “mass spectrometer” in which photographic plates were replaced by collection and electronic amplification of the small electrical currents produced by the beams of positively charged ions of each isotope. The technological advance allowed much more precise and accurate isotopic measurements. Alfred Nier not only made major contributions to mass spectrometer design but also made several discoveries that were critical to advances in geochronology. Nier in 1938 found that “common lead,” e.g., lead from lead ores, had significant variations in isotopic compositions. Earlier measurements of the mean atomic mass of lead from a variety of ore samples gave essentially identical results, leading to the assumption that all common leads must have ca. identical isotopic compositions. Nier demonstrated that relative to the non-radiogenic isotope, ^{204}Pb , ^{206}Pb , and ^{208}Pb tended to vary in a highly correlated way that fortuitously resulted in little or no variation in mean atomic mass. Nier further suggested that common lead must consist of a mixture of primeval lead of fixed isotopic composition dating to the time of the Earth’s formation, plus radiogenic lead generated by the decay of uranium and thorium after the Earth’s formation. This was a conceptual leap crucial to all subsequent estimations of the age of the Earth. In 1939 Nier turned his attention to uranium and lead in uranium ores, making a remarkably accurate measurement of the $^{238}\text{U}/^{235}\text{U}$ and $^{234}\text{U}/^{238}\text{U}$ ratios of uranium. Nier then combined the uranium isotope data with the lead isotope data from the same samples to calculate a remarkably accurate decay constant for ^{235}U . In 1941, Nier and his collaborators reported a $^{207}\text{Pb}/^{206}\text{Pb}$ age of ca. 2.6 Ga for a monazite from Manitoba, Canada. This was the first *isotopic* age determination for the antiquity of the Precambrian, and a rigorous minimum age for the Earth. Nier and his colleagues also reported lead isotope measurements for a wide array of lead ores. These data attracted the attention of E. K. Gerling, Arthur Holmes, and F. G. Houtermans all of whom realized that Nier’s isotopic data for lead ores could be used to estimate the age of the Earth. Gerling, Holmes, and Houtermans calculated ages for the Earth ranging from ca. 3.0 to 3.9 Ga on the (incorrect) assumption that the ore with the lowest $^{206}\text{Pb}/^{204}\text{Pb}$ and $^{207}\text{Pb}/^{204}\text{Pb}$ ratios approximated the isotopic composition of primeval lead. At this stage in the evolution of geochronology, isotope ratios were being measured by more or less modern techniques, but the amounts of uranium and lead were still measured by classical chemical methods. This was about to change dramatically.

The Discovery of Nuclear Fission and the Separation of Isotopes

Meanwhile, other momentous discoveries in nuclear physics were underway which would have profound implications for geochronology, both directly and indirectly. In 1933, only months before Marie Curie's death, her daughter and son-in-law, Irene and Frederic Joliot-Curie, bombarded aluminum with alpha rays. The aluminum captured alpha particles and emitted neutrons, producing a radioactive isotope of phosphorous. The phosphorous in turn decayed with a short half-life to a stable isotope of silicon. The Joliot-Curies had artificially transformed a stable element into a different, radioactive element. Many labs began bombarding a wide range of elements with various particles, including neutrons. Irene Joliot-Curie and Pavel Savitch, a visitor to her lab, bombarded uranium with neutrons and produced a radioactive product that appeared to have the properties of lanthanum. Conventional wisdom at the time dictated that products of irradiation should be within a few atomic mass units (amu) of the target element. Since lanthanum is ca. 100 amu lighter than uranium, the Joliot-Curie-Savitch result seemed highly unlikely, in fact impossible, even to Joliot-Curie and Savitch themselves. Had they been bolder, they might have realized that they had induced nuclear fission. The Germans Otto Hahn and Fritz Strassmann, who also doubted the original result, duplicated the experiments. They eventually positively identified barium (also about 100 amu lighter than uranium), plus several other elements, as products of the neutron irradiation – clear evidence that the atom had been split. The discovery of fission triggered another period of intense research, and with the onset of World War II, the “Manhattan Project,” and the development of nuclear weapons. An essential part of the Manhattan Project was development of isotope separation techniques to concentrate ^{235}U , the isotope of uranium susceptible to “induced fission” by neutron irradiation. The ability to separate isotopes would open the door to a major breakthrough in geochronology, the “isotope dilution method” for precise and accurate measurements of very small amounts of a wide range of elements.

General references: Harper (1973), Quinn (1995), Rhodes (1986), significant parts of this section are adapted with slight modification from Mattinson (2013a, 2013b).

The Isotope Dilution Method and the Development of Geochronology

After World War II many scientists recognized that the discoveries of military research could be applied to a wide range of research problems in physics, chemistry, and geology. One such scientist was Harrison Brown, who headed a group at the University of Chicago studying trace elements in meteorites. In addition to his interests in meteorite chemistry in general, Brown was familiar with the recent work on the age of the Earth using Pb isotopes. He thought that iron meteorites might contain Pb but not U, thus providing a true primordial isotopic composition of Pb from the early solar system. Key members of the group included Mark Ingram, a physicist and mass spectrometer expert, and graduate students Clair “Pat” Patterson and George Tilton. The group developed new, much more sensitive mass spectrometric techniques for measuring the isotopic compositions of small amounts of lead in meteorites and minerals from terrestrial samples (e.g., the mass spectrometry methods they developed reduced the amount of Pb needed for analysis by a factor of ca. 1,000 compared with Nier's earlier work). Brown's group also perfected the isotope dilution (ID) technique for accurately measuring low concentrations of Pb, Th, and U. In the ID technique, a known amount of a highly purified isotope of the element of interest is added to a sample, prior to any chemical separations. For example, a known amount of highly pure ^{235}U is added to a sample containing natural U, which is over 99 % ^{238}U . After separating U from all of the other elements in

the sample, the ratio of $^{235}\text{U}/^{238}\text{U}$ is measured by mass spectrometry, and the amount of ^{238}U in the sample can be calculated with high accuracy. The same approach is used for Pb, using a “tracer” or “spike” of a highly purified isotope of lead. The work led by Tilton on minerals such as zircon, sphene (titanite), apatite, and several other minerals from terrestrial granite was an immediate success, and fully published after some delay owing to “top secret” classification of the very existence of purified ^{235}U (Tilton et al. 1955). The Pb isotopic work on meteorites went more slowly owing to low Pb levels in most meteorite samples and high levels of Pb contamination in the environment. Patterson continued with the meteorite work, overcame the challenges of Pb contamination, and determined a ca. 4.55 Ga age for meteorites and the Earth (Patterson et al. 1955; Patterson 1956), quite compatible with modern measurements. The long quest to determine the age of the Earth had finally succeeded.

General references: Harper (1973), Lewis (2000), significant parts of this section are adapted with slight modification from Mattinson (2013a, 2013b).

50 Years of Refinement, Expansion, and Growth of Geochronology

At about the same time that Brown’s group developed the next generation of U–Th–Pb geochronology, similar techniques using advanced chemical separation, mass spectrometry, and isotope dilution were applied to the Rb–Sr and K–Ar parent-daughter systems. Rb and K were discovered to be “weakly radioactive” by 1906 but could only be exploited for geochronology by about the 1950s when instrumentation and methods had sufficiently improved. Also developed in the early 1950s was the carbon-14 dating method. By the mid-1960s these techniques were all well established.

The fifty years between 1963 and the present have seen, quite literally, an explosion in the amount of geochronological research, the diversity of methods, the quality of the analyses, and the sophistication of data interpretation. Major driving forces have included development of new instrumentation, analytical techniques, data analysis techniques, and, especially in the last decade, laboratory collaboration at national and international levels. ... depending on how one counts, close to 40 different dating methods are now available, spanning age ranges from months to billions of years. (Mattinson 2013a, pp. 5, 10)

Any detailed discussion of all these methods is far beyond the scope of this historical review. Interested readers can find more breadth and detail in the following sources: (1) general information, Allègre (2008), Dickin (2005), Faure and Mensing (2005); (2) recent publications, mostly on state-of-the-art techniques plus some history, Amelin and Ireland (2013), Condon and Schmitz (2013), Corfu (2013), Mattinson (2013a, 2013b), Nemchin et al. (2013), Schmitz and Kuiper (2013), and Schoene et al. (2013); and cross-references.

Zircon

John M. Hanchar*

Department of Earth Sciences, Memorial University of Newfoundland, St. John's, NL, Canada

Synonyms

[Cyrtolite](#); [Zirconium silicate](#)

Zircon (ZrSiO_4) is a common accessory mineral found throughout a wide range of igneous, metamorphic, and sedimentary rock types and unconsolidated sediments (e.g., beach or river sands). Zircon crystallizes in the tetragonal crystal system and contains the SiO_4 tetrahedra as the framework of its crystal structure. As such it is classified as an orthosilicate (or nesosilicate) mineral (Finch and Hanchar 2003) (Fig. 1).

A highly refractory mineral, zircon is resistant to chemical and physical weathering and chemical alteration over a wide range of pressures and temperatures in different geological environments. It often preserves geochemical information from multiple geologic events (e.g., internal structures and zoning) revealed using cathodoluminescence (CL) and back-scattered electron (BSE) imaging (Corfu et al. 2003) (Fig. 2).

Zircon often incorporates trace to minor element levels of non-formula elements, such as Hf, the rare-earth elements (REE) including Y, P, U, and Th in its crystal structure (Speer 1982; Hoskin and Schaltegger 2003). The Th/U ratio, for example, has been used to classify zircon as being igneous ($\text{Th/U} > 0.2$) or metamorphic ($\text{Th/U} < 0.1$) (Hartmann and Santos 2000); however, there are many exceptions to this rule. In particular, if other Th-rich minerals, such as monazite or allanite, crystallized prior to or at the same time as the zircon, those phases would preferentially incorporate Th over U and thereby change the amount of Th available for the zircon. This in turn would result in a lower Th/U ratio than would be expected.

Due to its sluggish diffusivity for virtually all impurity trace elements (Cherniak 2010), zircon retains a remarkable amount of geochemical information about the source region in which it crystallized (e.g., Speer 1982; Hoskin and Ireland 2000; Hanchar and van Westrenen 2007). The REE composition, for example, has been used to constrain the petrogenesis of zircon. In particular, using differences in the slope of the REE pattern for the heavy REE (HREE) on lognormal chondrite-normalized plots, it has been shown that zircon that crystallized in igneous environments has a steeper slope for the HREE than zircon that crystallized in high-grade metamorphic environments (Rubatto 2002; Rubatto and Hermann 2003; Whitehouse and Platt 2003).

Zircon is the premier mineral of choice for U-Th-Pb geochronology because common lead (i.e., ^{204}Pb) is excluded from its crystal structure during crystallization, whereas radiogenic Pb produced from the radioactive decay of U and Th is retained (Davis et al. 2003). This is due to the extremely sluggish diffusivity of Pb in crystalline zircon. Once zircon becomes metamict, however, the diffusivity increases which in turn allows the Pb ions to more readily diffuse out of the zircon

structure (Cherniak 2010). The effects of this damage can be quantified using Raman spectroscopy (Nasdala et al. 2006).

The physical and chemical durability of zircon is a major factor in it being the mineral by which many of Earth's oldest known rocks have been dated (e.g., Froude et al. 1983; Bowring et al. 1989; Wilde et al. 2001) and is also an important factor in zircon having been previously considered as a candidate ceramic waste form for the geologic disposal of excess plutonium from dismantled nuclear weapons (Ewing et al. 2003).

Amino Acid Racemization, Coastal Sediments

John Wehmiller*

Department of Geological Sciences, University of Delaware, Newark, DE, USA

Introduction

Amino acid racemization (AAR) dating has been applied to a large variety of coastal sediments representing a range of geological ages and depositional environments (Fig. 1). In most cases, samples analyzed for the extent of racemization are of biogenic origin (mollusks, foraminifera, mixed carbonate sediments, or corals). AAR has been applied to coastal sediments as young as a few hundred years and as old as several million years. The goals of these studies include as follows: (1) correlation and relative age assignments for Pleistocene coastal or shallow marine units, (2) assessing Quaternary tectonic deformation rates and/or relative sea-level histories, (3) deciphering the chronology of Pleistocene glacial advances in coastal regions, and (4) understanding Holocene sedimentary processes including age mixing. In most cases, multiple samples of different genera have been analyzed from each collection site, and relative ages are inferred from apparent clusters of D/L values (aminozones).

Topics reviewed here include the following categories, with representative references: (1) emergent deposits, active continental margins, such as the Mediterranean (Hearty et al. 1986, 2007) and the Pacific coasts of South America (Hsu et al. 1989) and North America (Wehmiller 2013); (2) emergent deposits and passive continental margins, such as Australia (Murray-Wallace 1995, 2000) and the Atlantic coasts of South America (Aguirre et al. 1995) and North America (Wehmiller 2013); (3) offshore deposits and passive margins (Murray-Wallace et al. 2005; Meijer and Cleveringa 2009; Wehmiller et al. 2010); (4) tropical islands and carbonate reefs (Hearty et al. 2007); (5) coastal regions affected by glaciations (Miller and Mangerud 1985; Kaufman and Brigham-Grette 1993; Refsnider et al. 2013); and (6) age-mixing studies in coastal regions (Wehmiller et al. 1995; Kosnik et al. 2009). The latter three topics are discussed in more detail in other entries (see ► [Eolianites](#), [Arctic](#), [Biostratigraphy](#)). AAR results are used to determine relative ages within a study region, but if associated with independent age calibrations (derived from U–Th, ^{14}C , or other numerical dating method), then AAR can be used to provide semiquantitative ages using appropriate model(s) for the overall kinetics of racemization.

AAR Studies of Active Continental Margins

Along the Pacific coast of North America, south of Cape Mendocino, strike-slip relative motion is related to the northwest motion of the Pacific Plate. Coastal units and marine terraces in this region usually record relatively low uplift rates (approx. <0.2 m/ka years) with a few notable exceptions in localized areas. North of Cape Mendocino, where plate convergence related to spreading from the Juan de Fuca Ridge dominates the region, ages for uplifted marine terraces suggest more

*Email: jwehm@udel.edu

Fig. 1 World map showing coastal regions where AAR studies have been conducted. Letters on map denote the following: A, active margins; P, passive margins; G, coastal areas influenced by glaciations; X, offshore studies. Solid circles on map identify tropical islands for which AAR data exist

variable uplift rates, occasionally as high as 1 m/ka years (Kennedy et al. 1982; Dupré et al. 1991; Muhs et al. 1992a, 2004).

Uranium-thorium dating of solitary corals has been applied to numerous marine terrace sites along the North American Pacific coast (Muhs et al. 2004). These U–Th results provide rigorous calibration for the regional aminostratigraphy, allowing age estimates for AAR results from other sites with no independent age control. Two fundamental principles regarding racemization were tested and evaluated using samples from Pacific coast terraces (Wehmiller et al. 1977; Kennedy et al. 1982): (1) D/L values in multiple taxa increase with increasing terrace elevation for vertical sequences of terraces, and (2) D/L values increase with decreasing latitude (increasing temperature) in samples of known equal age. Molluscan faunal assemblages indicative of local water temperatures at the time of formation of late Pleistocene terrace deposits also are age indicative because of their association with the marine climate record and associated calibrated AAR results (Kennedy et al. 1982). The original aminostratigraphic framework (Kennedy et al. 1982) was extended with results from uplifted terraces on the Baja California Peninsula (Keenan et al. 1987) and the Gulf of California (Ortlieb 1991). Regionally specific studies of AAR in uplifted terraces in Southern California include Santa Barbara County (Rockwell et al. 1992), the Palos Verdes Hills (Muhs et al. 1992b), and San Diego County (Kern and Rockwell 1992). Localized zones of unusually rapid uplift rates (up to ~5 m/ka) are inferred from the ages (AAR, C14, and U–Th) of terraces found along the northern margin of the Santa Barbara Channel (Wehmiller 1992, 2013).

The marine terraces along the South American Pacific coast between ~15° and ~30° S are influenced by the subduction of the Nazca Plate beneath the South American Plate. In the northern area (Peru) six distinct aminozones, estimated to represent ages up to ~900 ka, are recognized, with independent calibration using electron spin resonance (ESR) dating (Hsu et al. 1989). In the more southern region (northern and central Chile), five aminozones were recognized, the oldest estimated to represent an age of ~700 ka (Hsu et al. 1989). In several cases, multiple aminozones were identified within a single localized terrace sequence. The highest uplift rates in Peru (~0.5 m/ka) are

found where the Nazca Ridge is being subducted under that South American Plate (Hsu et al. 1989; Hsu 1992; Goy et al. 1992; Saillard et al. 2011). Uplifted terraces are highest above the southern flank of the Nazca Ridge, being lower both to the north and south of the local region of ridge subduction. To the south, terrace uplift rates are generally less than 0.2 m/ka (Hsu 1992; Ortlieb et al. 1996). In some cases these low uplift rates have resulted in terrace reoccupation, with deposits of at least two interglacial ages being found within what appears to be a single mapped morphologic unit (Leonard and Wehmiller 1992).

A broad regional study of AAR data in mollusks (*Glycimeris* and *Arca*) from uplifted marine deposits in the western and central Mediterranean spans a latitude range of $\sim 10^\circ$ and a longitude range of $\sim 25^\circ$ (Hearty et al. 1986). The AAR data cluster into five distinct aminozones, the second youngest being associated with four U–Th coral ages that cluster around 126 ± 7 ka, equivalent to marine isotope substage 5e (Hearty et al. 1986). More detailed studies of selected sites in the western Mediterranean (Torres et al. 2000, 2013) using modern analytical methods (see ► [Chromatography](#)), while consistent with the fivefold aminostratigraphy, indicate that variability in D/L values within an aminozone can occur because of age mixing and/or shell alteration.

Coastal Quaternary units are preserved intermittently around the North and South Islands of New Zealand, where active subduction and strike-slip faulting occur associated with the convergence of the Australian and Pacific Plates. AAR data from these sites were occasionally obtained on wood (Pillans 1990) but more often using marine mollusks (Ota et al. 1996; Bowen et al. 1998). Along the south shore of the North Island of New Zealand, up to four kilometers of Plio-Pleistocene sediments are exposed in the Wanganui Basin with at least five aminozones representing deposition over the past one million years (Bowen et al. 1998). Supporting chronologic data include magnetostratigraphy and fission-track dating of interbedded volcanic ashes. At least seven nearby uplifted marine terraces can be correlated with portions of the Wanganui section using associated AAR data (Bowen et al. 1998), and similar correlation can be made with aminozones on the South Island of New Zealand (Ota et al. 1996).

AAR Studies of Passive Continental Margins

The Atlantic margin of the United States ($\sim 45^\circ$ N to $\sim 24^\circ$ N) includes sites of some of the earliest AAR studies of Quaternary marine mollusks (Mitterer 1974; Muhs et al. 2004; Wehmiller 2013). Exposed Quaternary coastal units in this region occur within ~ 10 m of sea level, reflecting minimal tectonic deformation. Nevertheless, there are underlying structures that influence the pattern of Quaternary sedimentation, the Albemarle Embayment (eastern North Carolina) being one major example. The Quaternary section in the Albemarle Embayment is up to 100 m thick, thinning to no more than ~ 10 m to the north and south, over the Norfolk and Cape Fear arches, respectively. Combined U–Th, AAR, and Sr dating indicates that at least eight separate phases (aminozones) of sedimentation between ~ 2 Ma and ~ 100 ka are preserved in the Albemarle section (Wehmiller et al. 2010, 2012). To the south of the Albemarle, multiple coast parallel paleoshorelines are recognized, but fewer AAR aminozones (~ 3 – 5) are recognized, most likely because the record is thin and less complete. To the north of the Albemarle, a record of paleoshorelines and fluvial incision during multiple glacial-interglacial cycles within the Chesapeake Bay drainage system is preserved (Groot et al. 1990; Genau et al. 1994; Mirecki et al. 1995; Wehmiller 2013). Units dated by AAR in this region are found within approx. ± 5 m of present sea level. AAR data from the Delmarva Peninsula, combined with stratigraphic and geomorphic analysis, indicate that the Peninsula evolved in a southerly direction during the Pleistocene, responding to multiple cycles of fluvial incision and

valley filling during glacial-interglacial sea-level cycles. AAR data for beach shells in the US mid-Atlantic region demonstrate age-mixing processes associated with coastal dynamics and subsurface stratigraphy (Wehmiller et al. 1995).

AAR and associated radiocarbon, U–Th, or luminescence data exist for Quaternary coastal units on the western, southern, and eastern coasts of Australia, including some offshore marine cores (Murray-Wallace 1995, 2000; Murray-Wallace et al. 2001, 2005; Hearty and O’Leary 2008). AAR data for the southern coast can be grouped into at least four aminozones representing deposition during most of the Pleistocene. Whole-rock (eolianite) AAR age estimates combined with luminescence dating from the Coorong Coastal Plain and the mouth of the River Murray, South Australia, show that a series of coastal barriers have developed in this region over the past 500 ka in response to glacial-interglacial sea-level cycles (Murray-Wallace et al. 2001, 2010).

Extensive AAR data exist for coastal units on the western coast of Australia, primarily based on the analysis of eolianites, samples composed of nearly 100 % carbonate fragments (Hearty 2003; Hearty and O’Leary 2008; O’Leary et al. 2008). Six aminozones are recognized, spanning an interval from the Holocene (<10 ka) to over 500 ka. A global synthesis and discussion of the geochronology of the last interglacial (MIS 5e) shoreline (Hearty et al. 2007) include AAR data from multiple Australian sites and also sites from the central Pacific, western Atlantic, and the Mediterranean.

Hearty and Aharon (1988) and Kosnik et al. (2007, 2009, 2013) reported AAR data for samples from the Great Barrier Reef, offshore eastern Australia. These studies have focused on Holocene specimens, often using age-calibrated samples to establish the kinetics of racemization in different sample types. Kosnik’s studies also emphasize the use of AAR in evaluating the magnitude of age mixing within Holocene assemblages.

AAR data for the coastal plain of Argentina between ~35°S and ~55° S for multiple taxa identify both Holocene and Pleistocene aminozones (Rutter et al. 1989, 1990; Aguirre et al. 1995). Two Pleistocene aminozones are recognized, one representing at least a portion of the last interglacial high sea stand. Electron spin resonance (ESR) provides limited independent calibration. Last interglacial shoreline deposits are usually found between 10 and 15 m above sea level. AAR data indicate that some deposits, at elevations up to ~40 m, are older than the last interglacial. Holocene coastal/marine deposits are also found in this region, at elevations up to ~5 m, so there is ample potential for age mixing.

Carr et al. (2010) reported AAR data for marine mollusks and terrestrial gastropods from sites along the coast of South Africa. Optically stimulated luminescence (OSL) results provided the primary age control, indicating formation of beach deposits and associated dunes between 138 ± 7 ka and 113 ± 6 ka, at elevations up to ~8 m above sea level. AAR data, while limited, are consistent with these age estimates.

AAR Studies of Submerged Deposits, Continental Margins

AAR data for shallow submerged portions of the continental margins of Europe, Australia, North America, and Antarctica also exist. In many cases, these studies compare offshore data with results from nearby onshore sites. Along the US Atlantic margin, aminozones representing multiple intervals of deposition during the Pleistocene are encountered from offshore New Jersey, Maryland, Delaware, and North Carolina (Toscano and York 1992; Groot et al. 1995; Wehmiller et al. 2010; Miller et al. 2013). In most cases there are associated lithostratigraphic, paleontological, and geophysical data to aid in the environmental analysis of the AAR data. Sr-isotope age estimates

provide some qualitative calibration for some of the older (early Pleistocene) aminozones (Wehmiller et al. 2012; Miller et al. 2013). These continental margin records usually contain evidence of multiple transgressive-regressive cycles associated with sea-level changes during the Pleistocene, as in the case of southeastern Australia (Murray-Wallace et al. 2005), the North Sea (Meijer and Cleveringa 2009), and the Black Sea (Nicholas et al. 2011). AAR results from deeper water environments off northeastern Australia (Hearty et al. 2004) demonstrate the kinetic effects of different bottom water temperatures (see ► [Marine Sediments](#)).

Low-Latitude Carbonate Islands and Reefs

The stratigraphy and geochronology of deposits on numerous low-latitude islands from the Atlantic and Pacific Oceans have been studied using AAR, using either land snails, whole-rock analyses of carbonate eolianites (see ► [Eolianites](#)), or marine mollusks. In many cases the results contribute to the chronology of local eolianite (dune) formation, usually associated with local relative sea-level histories. Studies of Pleistocene units from Atlantic, Mediterranean, or Caribbean islands include Bermuda (Hearty et al. 1992, 2007), the Bahamas (Hearty and Kaufman 2000; Hearty 2010), Jamaica (Goodfriend and Mitterer 1993), Barbados (corals) (Wehmiller et al. 1976), Madeira (Goodfriend et al. 1996a), the Canary Islands (Zazo et al. 2002), and the Mediterranean region (Hearty et al. 1986; Hearty 1987; Rose et al. 1999). Pacific Island studies include Lord Howe Island (Brooke et al. 2003; Woodroffe et al. 2006), New Guinea (Hearty and Aharon 1988), and Hawaii (Hearty et al. 2000, 2007). AAR studies of Holocene corals from assorted localities establish the kinetics of racemization during the earliest phases of diagenesis (Hearty and Aharon 1988; Goodfriend et al. 1992; Hendy et al. 2012; Tomiak et al. 2013). The tropical temperatures at which these corals are found enhance the overall rate of racemization, allowing high-resolution kinetic studies.

Coastal Regions Influenced by Glaciations

Discussions of these regions will be found in separate entries (► [Arctic Environment](#), [Loess and Glacial](#)), but selected references for these areas are reviewed here (see Fig. 1).

High-latitude coastal regions that have been affected by glaciations reveal a complex record of Quaternary deposition. AAR-dated samples are often transported from their original site of deposition, but results from these samples can constrain histories of ice dynamics and local relative sea-level history. Along the Arctic margins of Pleistocene ice sheets, ice margin and sea-level histories are documented in northeastern Siberia, northwest Alaska, Baffin Island, Greenland, and Spitzbergen (Miller et al. 1992; Kaufman 1992; Kaufman and Brigham-Grette 1993; Funder et al. 1994; Brigham-Grette and Hopkins 1995; Goodfriend et al. 1996b; Kelly et al. 1999; Brigham-Grette et al. 2001; Gualtieri et al. 2003; Mangerud et al. 2008; Refsnider et al. 2013).

Along the southern margin of the Laurentide Ice Sheet, clusters of D/L values in mollusks identified multiple advances of ice in the Hudson Bay Lowland, including events that were recognizable only in transported samples found in glacial sediments (Andrews et al. 1983; Thorleifson et al. 1992). AAR data for in-place estuarine mollusks identified both pre- and post-last glacial fossiliferous deposits in the St. Lawrence valley (southeastern Canada) using AAR analyses of marine mollusks (Occhietti et al. 1996).

A long history of AAR study of sites along the southern margin of the Scandinavian Ice Sheet and associated sites in the United Kingdom exists. Miller and Mangerud (1985) and Sejrup et al. (2000) analyzed AAR in mollusks found in marine and glacial deposits of the North Sea, Norway, Denmark, Germany, and the Netherlands. Meijer and Cleveringa (2009) summarized AAR data for the region, generated by several laboratories over three decades. Bowen (2000) and Penkman et al. (2011, 2013) used AAR data to interpret the glacial, marine, and nonmarine records of the United Kingdom. Almost all of these studies demonstrate that multiple phases of deposition, either shallow marine or fluvial, are apparent in the regional record, extended back through the entire Pleistocene.

Application of AAR to high-latitude Southern hemisphere sites includes southern Chile (Clapperton et al. 1995) and Antarctica (Hart and Webb 1998; Forsberg et al. 2003; Gardner et al. 2006). Each of these studies includes AAR and other independent chronological information to reconstruct local histories of glacial advance and retreat. As with other high-latitude studies, the low temperatures of these regions result in very slow racemization kinetics, meaning that low D/L values are observed even in samples that are perhaps as old as 4 Ma.

Summary and Conclusions

The use of racemization in the study of Quaternary coastal environments and processes has a history almost as long as the history of the AAR dating method itself, as some of the earliest studies involved fossils from coastal sites along the US Atlantic coast (see Wehmiller 2013, for review). Regions of study range from polar to equatorial latitudes, with potential age ranges for application being determined by the effective temperatures in these climates. Many coastal studies, in particular, benefit from associated U–Th dating of associated corals (at low- or mid-latitude sites), the preferred sample type for U-series dating. In addition, AAR data from coastal studies have yielded important insights into geochemical and taxonomic factors that influence racemization, particularly in situations where long relative age sequences of samples are available. Extensive AAR study of major active continental margins includes marine terraces on the Pacific coasts of North and South America and the Mediterranean; passive continental margins include the Atlantic coasts of North and South America and much of the coast of Australia, including several long chronologic sections spanning the entire Quaternary. Studies of sites in high northern latitude regions in North America (Baffin Island) and Europe (United Kingdom, Scandinavia, and the southern North Sea) have been historically important for the development of AAR methods and have contributed substantial insights into the Quaternary glacial and climate history of northern hemisphere ice sheets. Data from lower-latitude sites provide a broad perspective for comparison with mid- and high-latitude results, and a large dataset exists for a variety of types of carbonate (marine and eolian) deposits on tropical islands from the Atlantic, Pacific, and Mediterranean. These latter results come from a variety of sample types not usually sampled from higher-latitude sites, and the rapid racemization at low-latitude temperatures permits high-resolution kinetic and age-mixing studies.

Volcanic Glass (Fission Track)

John A. Westgate*

Department of Earth Sciences, University of Toronto, Toronto, ON, Canada

Definition

Volcanic glass. An amorphous, noncrystalline solid produced by the rapid cooling of magma during a volcanic eruption.

Fission track in glass. An etched conical pit formed by the preferential solution of glass along a latent fission track, which, in turn, is formed by the spontaneous fission of ^{238}U or induced fission of ^{235}U .

General Considerations

Fission-track (FT) dating methods provide meaningful ages using silicic volcanic glass and are particularly applicable to the dating of young volcanics in calc-alkaline terrains where the $^{40}\text{Ar}/^{39}\text{Ar}$ method is less suitable due to low potassium values. Successful glass–FT ages have been obtained on tephra beds as young as Late Pleistocene and as old as Middle Eocene, as demonstrated herein, and the ability to date very fine-grained, typically contaminated, distal tephra has been an important boost to the geochronology of regions distant from volcanic centers – in both terrestrial and marine environments.

Fission tracks in glass are revealed by etching in hydrofluoric acid. They are conical pits due to the isotropic properties of glass and a track etch rate that is not much greater than the bulk etch rate. Shapes, as seen under an optical microscope, vary from circular to elliptical, depending on the orientation of the axis of the cone with respect to the polished surface (Fig. 1).

Volcanic glass must meet several conditions before meaningful FT dates can be determined (Faure 1977). The U concentration must be sufficient to give a statistically significant age. Tracks must be stable at ambient temperatures, true of glass, but partial fading of fission tracks (PTF) occurs in all glasses, and correction procedures must be applied to account for this condition. The glass should be free of microlites and other inclusions, which, upon etching, can resemble fission tracks. Furthermore, the glass surface area must be large enough to permit accurate measurement of the areal FT densities. Obsidian typically meets these criteria (Bigazzi and Bonadonna 1973; Doriguel et al. 1998), but glass shards in some tephra beds do not. Bubble-wall glass shards can be readily dated (Fig. 2a), but not pumiceous pyroclasts (Fig. 2b). The lower limit in grain size is $\sim 80\text{ }\mu\text{m}$. Uranium must be distributed uniformly throughout the glass, a requirement that can be assessed directly by laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) (Pearce et al. 2004). The glass must be unaltered, and, in the case of tephra beds, the shards must

*Email: westgate@es.utoronto.ca

Fig. 1 Induced fission tracks in a glass shard of Huckleberry Ridge Tuff, Kansas, USA (UT1366), as seen using an optical microscope. Parallel lines across glass shard are polishing scratches, purposely made to indicate the internal surface. The mean track diameter is $8.38 \pm 0.10 \mu\text{m}$

Fig. 2 (a) Bubble-wall glass shards of the late Pleistocene Youngest Toba Tuff (YTT), Indonesia, and (b) pumiceous pyroclasts from the late Pleistocene Sheep Creek tephra, Yukon, Canada. The latter tephra bed cannot be dated by glass–FT methods because of insufficient glass surface area, but tephra beds with glass shards similar to those of YTT are readily dated by fission tracks

belong to a single population; tephra beds with multiple glass populations, primary or reworked from earlier tephra deposits, do not provide meaningful FT dates. A unimodal glass population should be demonstrated by major- and trace-element analyses prior to FT dating. Contamination of

the sample by mineral grains, however, does not compromise the date because glass–FT methods are grain specific in the sense that the track data are gathered by examination of individual glass shards in each field of view under the microscope so that mineral grains can be readily recognized and ignored. The sample must not have been exposed to any post-depositional heating that would cause resetting of its fission tracks – a condition that could occur in geothermal areas or where tephra beds have been affected by high temperatures associated with emplacement of younger igneous bodies. As with all geochronologic studies, the stratigraphic and sedimentologic contexts of the deposit must be well established.

Silicic, hydrated glass shards of low vesicularity are ideal for FT dating. They are the most abundant phase of tephra beds; they are mostly homogeneous and rarely contain microlites or inclusions; they have uniform etching characteristics; and U contents typically range from 2 to 8 ppm for rhyolitic to dacitic glasses, enough to give statistically viable ages for tephra beds as young as Late Quaternary (Alloway et al. 2004a). Under conditions of rapid cooling during the eruption and storage at near-surface temperatures, geologically meaningful formation ages can be obtained. In addition, because fine-grained shards can be dated by glass–FT methods, the geochronology of regions far from volcanic centers can be tackled due to the common widespread distribution of silicic tephra beds (Westgate et al. 2007). One of the earliest successful examples of glass–FT dating involved the use of glass shards to determine the age of Bed 1 at Olduvai Gorge (Fleischer et al. 1965a, 1975). The FT age of 2.0 ± 0.3 Ma agreed with the K–Ar age of 1.75 ± 0.05 Ma, obtained earlier by Leakey et al. (1961).

Another important consideration in FT dating is the suitability of a glass standard. Although the Moldavite tektite is the formal glass age standard (IUGS Commission on Geochronology; Hurford 1990; Balestrieri et al. 1998), its practical use is limited by the requirement that all splits for distribution to FT laboratories must come from one single sample. Necessary attributes of an age standard are that it contains sufficient tracks to give a statistically meaningful age and that no PTF has occurred. It is doubtful that such a glass exists, especially hydrated glass, but the closest contender is the Jankov Moldavite. Other recommended age standards are Roccastrada R2V, macusanite, and the Japanese glass JAS-G1 (Balestrieri et al. 1998). The University of Toronto FT laboratory currently uses the Huckleberry Ridge tephra from Meade County, Kansas, USA, to monitor accuracy of its FT age determinations. This tephra bed has large glass shards with no mineral inclusions, high U content (~ 8 ppm), a reference $^{40}\text{Ar}/^{39}\text{Ar}$ age of 2.003 ± 0.014 Ma (2σ ; Gansecki et al. 1998), and abundant spontaneous fission tracks, making it a useful informal reference glass. PTF has occurred ($D_s/D_i = 0.81 \pm 0.02$ based on six samples; D_s is the mean diameter of spontaneous tracks and D_i is the mean diameter of induced tracks), but well-established correction procedures are available (see below).

Glass–FT Dating Methods

The most commonly used FT dating method is the zeta calibration method based on analysis of age standards (Hurford and Green 1983), which, in the case of glass–FT dating, is the Moldavite tektite with an age of 14.34 ± 0.08 Ma (Laurenzi et al. 2003, 2007). An age can be determined by measuring three areal track densities, spontaneous track density (ρ_s), induced track density (ρ_i), and induced track density of the dosimeter glass (ρ_d) or its muscovite external detector. The area is determined using an eyepiece graticule when the glass surface area is large, such as with obsidian and proximal tephra samples. Smaller glass shards require use of the point-counting technique

Fig. 3 Size frequency curves of FT diameters in glass shards of Huckleberry Ridge Tuff demonstrating partial track fading – the spontaneous tracks are much smaller than the induced. The mean diameter of spontaneous tracks is $6.85 \pm 0.10 \mu\text{m}$ ($n = 200$) compared to $8.38 \pm 0.10 \mu\text{m}$ ($n = 663$) for the induced tracks

(Naeser et al. 1982), in which case, an additional experimental error is involved (Bigazzi and Galbraith 1999).

Determination of ρ_s and ρ_i can be done in one of two ways: the population and population-subtraction methods (Wagner and Van den Haute 1992). In the former, the sample is split into two aliquots, one of which is heated to remove the spontaneous tracks, irradiated, and then used to obtain ρ_i . The spontaneous track density, ρ_s , is obtained from the unheated aliquot. Whereas this method is acceptable for obsidian, it is not good for hydrated glass shards. The differential heat treatment means that track-etching efficiencies for ρ_s and ρ_i are different and heating above 200°C drives off water and produces brittle glass shards which readily fracture when polished, reducing the glass surface area when etched. Surfaces with a network of fine fractures are also produced, hindering track recognition (Naeser et al. 1980). A better and recommended approach does not use any heat treatment. The induced track density, ρ_i , is calculated by determining the areal track density of the irradiated aliquot and then subtracting ρ_s .

Correction Methods for PTF in Glasses

Temperature is the dominant factor influencing the stability of latent fission tracks in natural glasses (Fleischer et al. 1965b). With progressive heating, latent tracks shorten and result in a reduced areal track density, giving an age that is too young. Even at ambient surface temperatures, PTF takes place (Naeser et al. 1980). Therefore, all glass-FT ages must be corrected for PTF. An example of a tephra bed (Huckleberry Ridge Tuff, UT1366) that has experienced PTF is shown in Fig. 3. The spontaneous fission tracks are distinctly smaller than the induced tracks.

Several procedures have been developed to correct for PTF (Arias et al. 1981; Storzer and Wagner 1969). Two are mentioned here. Experimental studies by Sandhu and Westgate (1995) demonstrated a near 1:1 relationship between ρ/ρ_o and D/D_o , where ρ_o and D_o are the original areal track density and mean track diameter, respectively. If the sample is etched to give $D_o (= D_i)$ in the range of 6–8 μm , the corrected spontaneous areal track density (ρ_{sc}) is given by

Fig. 4 Close correspondence between glass–DCFT and glass–ITPFT ages demonstrating a near 1:1 relationship. The regression line has $r^2 = 0.997$. See Table 1 for further details

$$\rho_{sc} \approx \rho_s \left(\frac{D_i}{D_s} \right) \quad (1)$$

Of the many tephra samples we have dated by this diameter-corrected FT method (DCFT), D_i/D_s values range from 1.10 (75 ka) to 1.41 (2 Ma), but there is no correlation between age and magnitude of this correction. The mean value of D_i/D_s is 1.22 ± 0.08 .

The isothermal plateau FT (ITPFT) method uses a single heat treatment of 150 °C for 30 days to correct fully for PTF (Westgate 1989). The FT age of a sample is proportional to ρ_s/ρ_i , and the point at which this ratio does not change with increasing time at a specified temperature – the plateau condition – signals a full correction for PTF and is confirmed by $D_s = D_i$. Kitada and Wadatsumi (1995b) showed that increasing the temperature to 165 °C for 5 days was enough to give a plateau age. Other time-temperature conditions used to correct for PTF are given in Westgate et al. (2007) with a cautionary note to the effect that plateau-annealing conditions should be such as to minimize structural damage to the glass because of potential negative effects on its etching characteristics – a long time–low temperature combination being favored.

Comparison Between Glass–FT Dating Methods

A comparison between glass–DCFT and glass–ITPFT ages is shown in Fig. 4 and Table 1. Good agreement exists and adds confidence to the validity of both methods. The heat treatment required in the ITPFT method increases the thermal stability of fission tracks so that an adequate etch requires a longer time compared to that required in the DCFT approach. As a result, the lower size limit of glass shards to be dated by the ITPFT method is $\geq 120 \mu\text{m}$ whereas shards as small as $\sim 80 \mu\text{m}$ can be dated by the DCFT method.

Accuracy and precision of glass–FT ages can be gleaned from Table 2. Ages range from 48 ka to 38 Ma and all are within $\sim 10\%$ of the mean age determined by other methods, mostly $^{40}\text{Ar}/^{39}\text{Ar}$ ages. Furthermore, all glass–FT ages agree with those ages derived by other methods at the 1σ criterion, with the exception of the Cindery Tuff. In particular, excellent agreement exists with the

Table 1 Comparison of glass–DCFT and glass–ITPFT ages

Giraffe tephra (UT2114, 2115)	37.42 ± 3.55	39.37 ± 3.53	Doria et al. (2011)

The population–subtraction method was used. Ages calculated using the zeta approach and $\lambda_D = 1.551 \times 10^{-10}$ year⁻¹. Zeta value is 301 ± 3 based on six irradiations at McMaster Nuclear Reactor, Hamilton, Ontario, using the NIST SRM 612 glass dosimeter and the Moldavite tektite glass (Lhenice locality) with an ⁴⁰Ar/³⁹Ar age of 14.34 ± 0.08 Ma (Laurenzi et al. 2003, 2007). Ages in Ma unless otherwise noted; 1σ given

⁴⁰Ar/³⁹Ar ages on the reference glasses, Jankov Moldavite, Roccastrada R2V glass and JAS-G1 obsidian (Balestrieri et al. 1998), as well as the Huckleberry Ridge Tuff.

Precision is within 10 % for the reference glasses but is ~15 % for the other tephra beds. Values are better when an eyepiece graticule can be used to determine area as opposed to the point-counting technique. Precision can be improved if DCFT and ITPFT ages are determined on a given tephra bed and a weighted mean age and associated error calculated using the standard inverse variance method (Bevington 1969). For example, the age of Giraffe tephra given in Table 2 is a weighted mean age and associated error of the two age determinations listed in Table 1.

Summary and Conclusions

Fission tracks are stable in glasses, as shown by their presence in silicic tephra beds of Middle Eocene age, but, over time, they suffer from PTF, even at ambient surface temperature conditions. As a result, a correction for ρ_s must be applied in order to obtain accurate FT ages. Several correction procedures have been developed; some are based on FT size data (e.g., DCFT method), others involve heat treatment (e.g., ITPFT method). Obsidian and glass shards of silicic tephra beds are the most common types of volcanic glass used in FT dating studies. Accuracy is within ~10 % of the age determined by other methods, mostly ⁴⁰Ar/³⁹Ar ages, and precision is in the range of 10–15 %. Both are acceptable. A limiting factor in attainment of good precision is the glass surface area available for counting fission tracks. This is usually not a problem with obsidians but is very relevant to glass shards of distal tephra beds. Introduction of the point-counting technique to estimate ρ_s and ρ_i has greatly helped in this regard. Acceptable ages can now be obtained on glass shards as small as ~80 μm. It follows, therefore, that these grain-specific FT methods are ideally suited to the dating of distal tephra beds, which are typically thin, discontinuous, fine-grained, and

Table 2 Accuracy and precision of glass fission-track ages: a comparison with other dating methods

Synonyms

[Detrital zircon analysis](#), [Zircon provenance](#)

Definitions

Detrital zircon: The mineral zircon (ZrSiO_4) is a common accessory mineral of many felsic igneous rocks. Because of its high relative hardness and chemical inertness, zircon mineral grains in a source rock can survive weathering and erosion to produce detrital grains that are transported to sedimentary deposition.

Uranium-lead radiometric dating: Some minerals, such as zircon, incorporate trace amounts of uranium in their crystal lattice when they form from a melt. The two principal isotopes of uranium (^{238}U and ^{235}U) are unstable and decay to form stable isotopes of lead (^{206}Pb and ^{207}Pb) over hundreds of millions of years. The rate of decay is known and measuring these isotopes in a sample allows the age of mineral formation to be calculated.

Sedimentary provenance: Sedimentary rocks are composed of detrital minerals derived from previously existing rocks. Some of these detrital minerals, for example, zircon (ZrSiO_4), preserve characteristics such as chemistry or radiometric age that can help identify the original rock source, or protosource, of those minerals when compared with data from previously analyzed rocks. In some cases, the detrital grains may be the only remaining evidence of the original rock. Integrating protosource information with other information such as petrology, paleogeographic reconstructions, and other detrital zircon data can build interpretations on the history, or provenance, of sedimentary detritus from protosource to final deposition.

Introduction

Sedimentary rocks are records of surface conditions and processes during Earth's history. Along with bulk physical features and chemical properties, the composition of the detrital mineral grains in sedimentary rocks has long been recognized as important information in understanding the origin and depositional processes of that sedimentary rock – information that can build interpretations about ancient environments and the ancient location of mountain belts and continents.

Descriptive studies and provenance interpretations of sedimentary rocks have traditionally focused on the heavy mineral or accessory phases as having characteristics that are considered diagnostic of origins, environments, and tectonic settings (e.g., Rittenhouse 1943; Morton and Hallsworth 1994). Zircon (ZrSiO_4) is especially useful because of a common distribution in most sedimentary rocks and its retention of chemical and isotopic features through most geological

*Email: keith.sircombe@ga.gov.au

processes to the point of melting. The robustness of the uranium-lead (U-Pb) radiometric system in zircon has been particularly useful, as an age of a mineral grain is a proxy for the source rock where it formed.

The techniques to measure the U-Pb age of detrital zircon have developed considerably in the last 50 years to where techniques are relatively inexpensive, rapid, and widely applied. Applications typically include the development of regional, and sometimes global, provenance and evolution models with a highlight being the discovery of the oldest terrestrial materials that provide a unique window into the early Earth. Recent studies are increasingly focused on refining the interpretation of those models with the integration of other analytical techniques or detailed study of modern analogues in order to test assumptions and understand potential biases.

Historical Development of Analytical Methods

The development of detrital zircon geochronology parallels, and in some cases has driven, the broader development of isotopic analytical equipment and methods (see Gehrels [2012](#), Ireland [2013](#), Nemchin et al. [2013](#), and the references therein for more descriptions of analytical methods and their development). The emergence of mass spectrometry equipment for applied geoscience research in the 1960s saw initial multigrain studies of detrital zircons as a reconnaissance tool in North American geology, e.g., Ledent et al. ([1964](#)) and Houston and Murphy ([1965](#)).

As equipment and methods developed through the 1970s and 1980s, analysis of single grains or even parts of single grains became possible with increasing precision initially via the labor-intensive chemical treatment of isotope dilution thermal ionization mass spectrometry (ID-TIMS) methods (e.g., Ross and Parrish [1991](#); Gehrels et al. [1995](#)). The emergence of secondary ionization mass spectrometry (SIMS) and laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) analytical equipment in the 1980s and 1990s revolutionized detrital zircon geochronology with rapid in situ analysis of small portions of individual grains.

The increasing speed of data collection also enables the collection of larger, statistically valid, datasets. The power of the in situ techniques was illustrated early in their development with the discovery of Hadean detrital zircon from Archean-aged metasedimentary rocks at Mt. Narryer in Western Australia (Froude et al. [1983](#)) and nearby Jack Hills (Compston and Pidgeon [1986](#)) using a Sensitive High Resolution Ion Microprobe (SHRIMP). In these samples, Hadean-aged grains may only form a few percent of the total detrital zircon population (which itself was typically <0.1 % of the total rock). The larger number of single-grain analyses possible with the in situ technique meant that it was more likely to find such rare occurrences.

Detrital zircon geochronology applications and techniques have expanded rapidly in the first decade of the twenty-first century, particularly with improvements in LA-ICP-MS equipment such as multi-collectors and technique refinements including measurement of common Pb (see Košler et al. [2002](#); Gehrels et al. [2006](#), [2008](#); Frei and Gerdes [2009](#) for further details of methodology development). Although solutions for the remaining issues around standardizing data acquisition, processing, and reporting are still being pursued (Horstwood [2008](#)), hundreds of papers based on detrital zircon geochronology are published every year.

Biases and Validity, Statistics and Interpretation

Detrital zircon geochronology is founded on the assumption that analyzed samples are representative of the protosource and that large datasets provide statistically valid quantitative information on proportions that accurately reflect the mass balance of detritus through the “sediment factory” (von Eynatten and Dunkl 2012). In reality, there are many potential natural and artificial biases that need consideration (Fedó et al. 2003).

The first set of natural biases relate to the origin of zircon itself. Zircon is preferentially formed in felsic igneous rocks so mafic protosources will be naturally underrepresented in zircon-based provenance analysis. Furthermore, whole regions may have marked enrichment in zircon content which, given the robust nature of the mineral, can dominate subsequent sedimentary units for aeons. For example, zircons from the granites emplaced during the Grenville Orogeny in eastern Laurentia around 1,150–1,050 Ma have been a dominant mode in subsequent Appalachian sedimentary history despite complex accretion tectonics through the Paleozoic (Moecher and Samson 2006).

A second set of natural biases occur with the sedimentological processes of weathering, transport, and deposition. Detrital zircon is assumed to have the same provenance as quartz and feldspar grains that form the bulk of a sedimentary rock although it is well known that denser zircon grains have higher settling velocities in a transporting fluid (Garzanti et al. 2008, 2009). Lawrence et al. (2011) demonstrate modern hydrodynamic fractionation within the zircon fraction using five samples taken from different locations on the same dune bedform in the Amazon River with significant difference in the proportions of age components (Fig. 1). Correlations between age and grain size of detrital zircons have also been shown in ancient sedimentary units (e.g., Gehrels et al. 1996; Sircombe et al. 2001).

Several studies have specifically targeted modern fluvial sedimentary deposits to illustrate potential biases against true proportionality. Cawood et al. (2003) and Sláma and Košler (2012)

Fig. 1 Variation in ratios of detrital zircon U-Pb age groups against grain size (phi) from a single dune bedform in the lower reaches of the Amazon River. *Diamonds* show ratio of ages >1,300 Ma against ages younger than 400 Ma, *squares* show ages >1,300 Ma against Grenvillian ages, and *triangles* show Grenvillian ages against ages younger than 400 Ma (Figure from von Eynatten and Dunkl (2012), based on Lawrence et al. (2011))

examined a series of detrital zircon samples from rivers in southern Western Australia and Scotland respectively that crossed major geological boundaries to illustrate the persistence of zircon sourced in the upper catchments. Whole catchment studies in central Nepal (Amidon et al. 2005) and in the Colombian foreland (Saylor et al. 2013) indicate that proportions of detrital zircon in modern fluvial sediments accurately represent the current exposure of potential protosources and their relative zircon fertilities. In comparison, a study of detrital zircon in the major tributaries of the Indus River, Pakistan, indicates less certain direct pathways between current exposure of bedrock and zircon age components in modern fluvial sediments (Alizai et al. 2011). Intriguingly, differences are attributed to temporal changes in the catchment regions such as intensity of monsoon rain linked with erosion rates with an estimated transport time of 5–10 ka.

DeGraaf-Surpless et al. (2003) in the Methow Basin in northern Washington and southern British Columbia and Smith and Gehrels (1994) in the Roberts Mountains allochthon, Nevada, demonstrate correlations between sedimentary maturity or lithofacies and expected age distribution. More mature sediments such as arenites generally contain the broader range of zircon age components, but closely spaced samples are relatively similar. Conversely, more immature sediments such as fluvial sandstones contain narrower ranges of zircon age components, but related samples are more dissimilar. These results indicate that more samples need to be collected for immature sediments to represent possible provenances.

Sample Preparation

Sample processing and mineral separation methods are a potential source for artificial biasing of a detrital zircon sample.

Rock crushing and milling is the typical first step for indurated sedimentary rocks. Early studies in granites suggest that there is little or no biasing of zircon caused by simple mechanical crushing (Larsen and Poldervaart 1957). However, more recent work (Hay and Dempster 2009) indicates substantial loss of any low-temperature or altered zircon present.

Density separation is a common second stage of sample preparation using water flow in a Wilfley concentration table (Niebur and Fell 1982), elutriation tubes (Frost 1959; Van der Westhuizen et al. 1993), or settling rates in various heavy liquids (Krumbein and Pettijohn 1938; Callahan 1987). Sláma and Košler (2012) explicitly tested for preferential loss of the small-grain fractions in a synthetic detrital zircon sample using Wilfley table and heavy liquid processes. They demonstrate that the Wilfley table process itself did not cause preferential loss, although heavy liquid separation alone did, possibly due to any electrostatic buildup during handling of the sample more likely to affect the smaller grains.

The typical third stage of zircon separation uses Frantz magnetic barrier separators to differentiate zircon based on magnetic susceptibility and the correlation between concordance and low or negative magnetic susceptibility (Silver 1963). Using a sample with a bimodal age distribution, Sircombe and Stern (2002) demonstrated the potential for biasing a detrital zircon age distribution in various magnetic fractions.

The final stage of sample preparation involves manual manipulation to mount individual zircon grains for analysis. Moecher and Samson (2006) discuss the biases that may occur with the often inadvertent preference for larger grains that are easier to manipulate and sufficiently large for in situ analysis. Preference for larger grain sizes is also demonstrated in interlaboratory calibration tests (Košler et al. 2013). Unless smaller grains are deliberately targeted, typical grain sizes >100 µm are chosen to accommodate ablation pits of 20–50 µm diameter.

Cathodoluminescence imaging of sectioned zircon is vital to understand the evolution of single grains and better interpret the resulting analyses (Hanchar and Miller 1993). Although the volume of

detrital zircon samples may make this process more laborious, the need for this level of understanding is also critical in provenance studies and provides extra dimensions to the age data (Hietpas et al. 2011).

Analytical Protocols

The protocol for analyzing detrital zircon samples has a profound effect on how the acquired data should be interpreted, and there are two principal strategies (Fedo et al. 2003).

The first strategy is “qualitative” where data are sought from every component in the population, typically guided by color, morphology, and internal structure (e.g., Gehrels and Dickinson 1995; Åhäll et al. 1998). This approach reduces the chance of missing a provenance component (Gehrels 2000) although it means data may be unsuitable for subsequent statistical comparison with other samples (Sircombe and Hazelton 2004).

The second strategy is a “quantitative” approach where a large number of grains are analyzed in an attempt to represent the true proportions in the population. At least 59 randomly selected grains need to be analyzed to reduce the probability of missing 1 in 20 components to 5 % (Dodson et al. 1988). This value was widely used; however, the formula has been reevaluated (it had been originally intended to describe searching for the *oldest* component, not all possible components), and the number of analyzed grains required to reach the same level of confidence should be 117 (Vermeesch 2004). However, this is the worst-case scenario that assumes randomly selecting grains from a uniform distribution of potential ages across all geological time. There are some experiments on natural and synthetic samples that suggest that >100 analyses are not required to reliably detect a small component in the detrital zircon population because provenances will not be uniformly distributed through time (Link et al. 2005; Sláma and Košler 2012; Košler et al. 2013).

Alternatively, given the inherent natural and artificial biases making true representation unlikely regardless of the number of single-grain analyses, a third approach is to combine both the quantitative (e.g., 35–70 grains) and qualitative strategies (Andersen 2005). A consensus on best practice in selecting the number of detrital zircon grains to analyze is yet to be resolved.

The two inherent features of U-Pb isotopic data are discordance and age-dependent precision which need to be accounted for in processing detrital zircon age data. It is typical, but subjective, to filter discordant data at 5 % or 10 % and step between calculating ages based on the $^{206}\text{Pb}/^{238}\text{U}$ ratio below 1,000 Ma and the $^{207}\text{Pb}/^{206}\text{Pb}$ ratio above. Nemchin and Cawood (2005) suggest a more objective and reproducible method using the concordia age calculation (Ludwig 1998) on each individual analysis to combine $^{206}\text{Pb}/^{238}\text{U}$ and $^{207}\text{Pb}/^{206}\text{Pb}$ ages and provide a probability of discordance for weighting the precision.

Visualization

The growth of detrital zircon datasets presents challenges to visualize, interpret, and compare large quantities of age data.

Because standard Wetherill and Tera-Wasserburg concordia charts quickly become obscured with large amounts of scattered detrital zircon data, the typical approach is to use a single age variable – to visualize the data using histograms or density distributions (although there are alternative visualization tools, see Sircombe 2006).

The typical approach to visualizing detrital zircon data is the probability density distribution or plot created by summing a series of normal distributions with means and standard deviations based on individual analyzed ages and their uncertainties (originally applied to detrital zircon fission-track data by Hurford et al. (1984) and U-Pb age data by Dodson et al. (1988), but likely based on earlier work in Ar/Ar analysis, e.g., Jessberger et al. (1980)). Building on the observations of Galbraith

Fig. 2 Comparison of visualization tools for a set of detrital zircon U-Pb ages from Hong Kong. Kernel density estimations (KDE) in *blue-shaded areas*, probability density plots (PDP) in *black lines*, histograms in *light-gray rectangles*, and individual ages illustrated by *circles* along x-axis (From Fig. 4 of Vermeesch (2012))

(1998) with fission-track geochronology, Vermeesch (2012) explained that probability density distributions are not true density estimates and established a kernel density estimation visualization that sums a calculated and uniform distribution for each analyzed age (Fig. 2).

Interpretation

A common aim of detrital zircon analysis is to extract ages to correlate with potential protosources using objective and reproducible deconvolution methods such as the maximum-likelihood mixture modeling of Sambridge and Compston (1994) or Bayesian mixture modeling (Jasra et al. 2006).

Increasing volumes of detrital zircon geochronology data are driving greater use of comparison methods and measurements of similarity to investigate the relationships among samples. Simple “eye-ball” comparison of plotted detrital zircon age distributions is neither objective nor reproducible.

A commonly used similarity comparison method uses a Kolmogorov-Smirnov (K-S) goodness-of-fit test based on the maximum distance between the cumulative probability distributions of samples being compared (Berry et al. 2001). While broadly used (e.g., DeGraaf-Surpless et al. 2003; Amidon et al. 2005; Dickinson and Gehrels 2009), the K-S method is sensitive to proportions of components and may produce counterintuitive results (Gehrels 2012). Vermeesch (2013) also discusses that the *p*-value generated by a K-S test to test if a hypothesis is statistically likely or not may be too simplistic and vulnerable to sample size effects.

Increasingly complex methods have also been developed, such as kernel estimation functions applied to detrital zircon age distributions to calculate similarity and the probability of being sourced from the same population (Sircombe and Hazelton 2004). Principal component analysis has also been applied to large datasets (Sircombe 2000b), although Vermeesch (2013) discusses the mathematical constraints of this approach and develops a broader multidimensional scaling (MDS) method. This approach can illustrate potential relationships between samples and protosources with a visualization similar to geochemical mixing models (e.g., Fig. 3; Che and Li 2013).

Fig. 3 Multidimensional scaling (MDS) map using the statistical technique of Vermeesch (2013) illustrating the similarity relationships between detrital zircon geochronology distributions in Chinese Loess Plateau samples (*blue circles*) and potential protosources (*blue stars* and *red circles*). *Blue arrow* shows possible binary mixing between sources in the Northern Tibet Plateau (NTP) and Gobi Altay Mountains (GAM) which are dominated by ~450 Ma and 350–250 Ma age modes, respectively. The *red line* shows the marked difference with samples from the Mu Us Desert (Stevens et al. 2013) which have dominant 200–100 Ma age modes (From Fig. 3 of Che and Li (2013))

Applications

Detrital zircon geochronology is applied to a wide range of geoscience questions (Fedó et al. 2003; Gehrels 2012), which can be broadly characterized as follows.

Geological Reconnaissance

Detrital zircons can provide useful geological insights into very broad regions such as desert sands in Central Australia (Pell et al. 1997) or ice-rafted drop stones in the North Atlantic Ocean (Small et al. 2013). Reconnaissance studies can also extend geological insight into regions that are physically obscured by ice in Antarctica (e.g., Goodge et al. 2002; Veevers et al. 2008; Palmer et al. 2012) or politically inaccessible (e.g., North Korea, Wu et al. 2007).

Stratigraphy, Chronostratigraphy, and Basin Evolution

A sequence of sedimentary units can provide critical information about the geological evolution of a sedimentary basin provided that the sequence can be adequately delineated through time. Detrital zircon geochronology can be used to provide an absolute chronological framework with maximum deposition ages and potential identification of disconformities, particularly in Precambrian rocks where biostratigraphy is limited.

The concept of a maximum age of deposition is based on the principal of inclusions – the deposition of the sediment itself must have occurred *after* the age of the youngest detritus in the

sediment. A cross-cutting relationship such as a dateable igneous intrusion can establish a minimum age of deposition (i.e., sediment deposition must have occurred *before* the intrusion).

However, the premise of the maximum age of deposition is founded on several assumptions, and seeking other lines of evidence to validate age bracketing of a sedimentary unit is advisable. The calculation of the maximum age itself from a given set of detrital zircon U-Pb age data can be conducted in several ways, yielding a wide variety of results (Dickinson and Gehrels 2009; Tucker et al. 2013).

There is no constraint on lag time between the formation of the youngest zircon and its deposition. Modern beach sand on the eastern Australia passive margin found a 250-million-year gap between the youngest zircon and modern deposition (Sircombe 1999). The assumed rapid transport of relatively young detritus into basins in active tectonic settings (Cawood et al. 2012) has been demonstrated for Mesozoic sequences from the Colorado Plateau that also have biostratigraphic constraints (Dickinson and Gehrels 2009). However, Cawood and Nemchin (2000) illustrate that tectonic activity can uplift and erode older sources just as readily as contemporaneous sources with a sequence of detrital zircon geochronology in the Perth Basin, Western Australia, where the stratigraphically youngest units have older apparent maximum deposition ages than stratigraphically older units.

Sudden change in detrital zircon age distributions can also be suggestive of hidden gaps in the sequence. This is demonstrated in the detrital zircon age distribution from a sequence of samples in the Paleoproterozoic Hurwitz Group in the western Hudson Bay region of Northern Canada that changes from Archean-dominated to a Paleoproterozoic-dominated with suggestions of a depositional hiatus of up to 150 million years (Fig. 4, Davis et al. 2005).

Provenance Analysis and Sedimentary Processes

Attempting to understand the provenance of sedimentary detritus also prompts greater understanding of the sedimentary processes transporting material between source and deposition. One recurring feature of detrital zircon geochronology is evidence of exceptional long and persistent transport pathways through geological history.

Building on lithostratigraphic indications of large river systems in Proterozoic Laurentia (Young 1978), analysis of detrital zircon in the Shaler Group on Victoria Island in the western Canadian Arctic revealed a prominent Mesoproterozoic component that is interpreted as being sourced from the Grenvillian Orogeny ~3,000 km away on the modern eastern margin of North America (Rainbird et al. 1992). Further work in similarly aged sedimentary units across North America has confirmed this premise and developed a model of a massive mountain building coupled with high rates/volumes of erosion and dispersion in an ancient environment with strong chemical weathering and lacking soil-binding vegetation (Rainbird et al. 2012; Fig. 5)

Another massive orogenic belt accompanied by rapid erosion and vast dispersion is seen in the widespread and often dominant occurrence of Neoproterozoic-aged zircon in Neoproterozoic to modern sedimentary basins throughout the former Gondwana supercontinent in Australia, India and the Himalaya, Africa, and South America (e.g., Ireland et al. 1998; Sircombe 1999; Avigad et al. 2005; Squire et al. 2006; Veevers et al. 2005a, b Myrow et al. 2010).

These extraordinary pathways are associated with environments prior to the evolution of terrestrial vegetation, but a modern analogue of a continental-scale sedimentary pathway is seen with the persistence of Cenozoic-aged zircon from the Andean orogenic margin thousands of kilometers downstream in the modern Amazon River (Mapes 2009; Lawrence et al. 2011).

Fig. 4 Stratigraphic column of the Hurwitz and Kiyuk groups in the western Churchill Province, Nunavut, Canada, illustrating a marked change in detrital U-Pb zircon ages between the Kinga Formation and the Watterson Formation interpreted as a major change in sedimentary provenance (From Fig. 2 of Davis et al. (2005))

Tectonic and Paleogeographic Reconstructions

Detrital zircon age data have been applied in the last 20 years to testing and refining often controversial models of reconstructing the Rodinia supercontinent based on lithostratigraphic and paleomagnetic evidence (Li et al. 2008).

Examples of intercontinental correlation include:

- 1,610–1,500 Ma detrital zircon ages in the Mesoproterozoic Belt-Purcell Supergroup of western North America do not have a likely local source in contemporaneous Laurentia and are correlated

Fig. 5 Geological map of North America illustrating interpreted extremely long sedimentary pathways from Proterozoic orogens in modern southeast to basins in modern northwest based on detrital zircon geochronology (From Fig. 29.2 of Rainbird et al. (2012))

with protosource rocks of similar age in central and northeastern Australia (Ross et al. 1992; Blewett et al. 1998; Ross and Villeneuve 2003).

- Alternatively, 1,600–1,300 Ma detrital zircon in the Transantarctic Mountains of East Antarctica, along with other isotopic evidence, is linked with distinctive sources in Laurentia/North America to support the SWEAT (Southwestern United States and East Antarctica) model of Rodinia configuration (Goodge et al. 2004 and 2008). A more recent study of detrital zircons in the Belt-Purcell Supergroup suggests further modifications to this model (Stewart et al. 2010).
- The location of the South China block in Rodinia configurations is also controversial with some models placing it as the “missing link” between eastern Australia and Laurentia (Li et al. 2008).

Paleomagnetism supports this configuration, but because paleolongitude is unconstrained, alternative models with the South China Block linked with Northeastern India and Western Australia have been proposed (e.g., Yang et al. 2004). Detrital zircon analysis has provided further support for the latter models with noted age components in Neoproterozoic sedimentary units exotic to South China similar to those found in India and East Antarctica (Yu et al. 2008). The regional correlations may also persist into Gondwana reconstructions with detrital zircon in Paleozoic sedimentary units also sharing similarity with detrital zircon from units in Western Australia (Duan et al. 2011; Cawood et al. 2013b). Similarly, detrital zircon correlations are made between the Lhasa terrane in Tibet and northwestern Australia, suggesting a complex formation and breakup of the Gondwana margin through the Proterozoic and Paleozoic (Zhu et al. 2011).

Crustal Evolution

The ever increasing volume of detrital zircon age data can be used to explore broader questions about the evolution of the Earth's crust as a whole (Cawood et al. 2013a). The abundance of certain age components, albeit with an acknowledgment of possible sampling bias, is considered as a proxy for the volume of orogenic zircon-producing activity. Studies such as Condie et al. (2009a) and Voice et al. (2011) have collated up to nearly 200,000 individual detrital zircon analyses from around the world (Fig. 6). Prominent age components identified in these data indicate that crustal evolution is punctuated by episodic orogenic/magmatic events correlated with supercontinent amalgamation (Condie and Aster 2010). Apparent gaps in the distribution, such as around 2,450–2,200 Ma, may also be indicative of broader whole-earth processes (Condie et al. 2009b).

Early Earth

The discovery of Hadean-aged detrital zircon in the Narryer Terrane in Western Australia (Froude et al. 1983; Compston and Pidgeon 1986; Dunn et al. 2005) is a major achievement of detrital zircon geochronology. These rare grains provide a unique window into the geochemical processes of the earliest Earth, and considerable effort has been made to find and analyze more of these grains (Harrison 2009). The oldest terrestrial material analyzed to date is a detrital grain from the Jack Hills at $4,404 \pm 8$ Ma (Wilde et al. 2001). Hf and oxygen isotopic analyses of these detrital grains have been interpreted as indicating that continental crust had formed (Harrison et al. 2005) and a liquid hydrosphere was present at or near the surface (Mojzsis et al. 2001) within a few hundred million years of the Earth forming. Although evidence remains limited (Nutman 2001; Valley et al. 2006), these results are tantalizing because such surface conditions are considered prerequisites for the emergence of life. Further work is required, especially in other localities where occurrences of Eoarchean- and Hadean-aged detrital zircon have also been found such as:

- Beartooth Mountains, Montana (Mueller et al. 1998).
- Yilgarn Craton, Western Australia (Nelson et al. 2000; Crowley et al. 2005; Thern and Nelson 2011).
- Slave Craton, Northern Canada (Iizuka et al. 2006).
- Sao Francisco Craton, Brazil (Hartman et al. 2006).
- Several locations in China (e.g., He et al. 2011, Huang et al. 2013, and references therein).

Fig. 6 A compilation of global detrital zircon age data illustrating the cyclical occurrence of prominent peaks at I. 300–100 Ma, II. 700–500 Ma, III. 1,200–1,000 Ma, IV. 2,000–1,700 Ma, and V. 2,700–2,500 Ma (From Fig. 1 of Voice et al. (2011))

Summary and Future Developments

The development of highly productive U-Pb analytical methods in the last 30 years has provided the tools for a wide range of researches into sedimentary provenance and basin evolution using detrital zircon geochronology. Applications include geological reconnaissance in large, poorly constrained regions and stratigraphic correlations building toward paleogeographic reconstructions of ancient supercontinents. Large-scale geochronology data acquisition also potentially provides information about global crustal evolution and has enabled the discovery of rare, but significant, remnant zircon from the Hadean Eon.

Detrital zircon geochronology provides insight into, and is in turn constrained by, an understanding of sedimentary processes and the potential for biasing. Although a common constituent of sedimentary rocks, zircon's typical petrogenesis in felsic igneous or metamorphic rocks limits the representation of mafic igneous events in a detrital age distribution. Processes of sediment formation

and transport have also been shown to bias distribution. Sample acquisition and processing needs to be carefully considered and monitored to avoid potential artificial biasing.

Although increasing acquisition of data brings new opportunities to compare and contrast a wide range of datasets, the volume of data being managed, visualized, and interpreted poses new challenges. Data visualization and interpretation tools have recently emerged, although further development is required to build toward standard usage of these tools.

Age of the Earth

Peter Barry* and Larry Taylor

Department of Earth and Planetary Science, University of Tennessee, Knoxville, TN, USA

Synonyms

Accretion time of Earth; Earth formation age; Planetary differentiation; Timing of core formation

Definition

Current constraints on the *age of the Earth* suggest accretion began approximately 4.54 ± 0.05 b.y. a., shortly after the formation of the solar system (~ 4.567 b.y.a.). However, the exact accretion time of Earth is difficult to determine, with predictions from different accretion models ranging from a few million up to about 100 m.y. after the formation of the solar system. Not surprisingly, our understanding of the *age of the Earth* is deeply rooted in our overall understanding of planetary science, particularly in our ability to accurately date meteorites using various radiogenic chronometers (e.g., U–Pb). The present-day best estimate for the *age of the Earth* is not decidedly different than the initial estimate of 4.55 ± 0.07 b.y.a. made by Patterson in his pioneering 1956 work. However, the resolution of the U–Pb isotope system is still not high enough to distinguish between very small age variations that may potentially separate the Earth, planets, and planetary bodies (e.g., meteorites). As a result, the exact timing of Earth formation is still a hotly debated issue, due in large part to the fact that the first ~ 500 m.y. of Earth history are not well preserved (Halliday 2004) in the terrestrial rock record. The oldest known materials on Earth are zircons from Western Australia, dated at 4.404 ± 0.008 m.y. (Wilde et al. 2001); however, terrestrial data of this age are limited and as a result this time period is shrouded in mystery.

In order to circumvent the lack of data available for early Earth history, geochronologists rely heavily on theoretical modeling and limited geochemical constraints from short-lived radionuclides to decipher the absolute timing of Earth formation. Xenon (^{129}Xe and ^{136}Xe) excesses in Earth's atmosphere suggest identifiable contributions from the decay of the short-lived radionuclides ^{129}I and ^{244}Pu , but in quantities considerably lower than predicted from abundances observed in meteorites. This implies that Earth did not achieve isotopic closure of the I–Pu–Xe system until ~ 100 m.y. after the formation of the solar system (Pepin and Porcelli 2006), an observation in agreement with $^{235}\text{U}/^{238}\text{U}$ – $^{207}\text{Pb}/^{206}\text{Pb}$ chronological methods (Allegre et al. 1995).

A slightly different approach is to use the onset of differentiation and core formation to define the exact *age of the Earth*. In this regard, the U–Pb and ^{182}Hf – ^{182}W isotope systems are the most useful as they can potentially reveal information about the timing of core formation. However, these chronometers are unable to differentiate between early accretion coupled with late core formation and late accretion coupled with simultaneous core formation. Nonetheless, the ^{182}Hf – ^{182}W system unambiguously dates core formation between 10 and 15 m.y. after the

*Email: peter.barry@utk.edu

formation of the solar system (Halliday 2004; Yin et al. 2002) and, as a result, indirectly constrains accretion timescales.

Accurately dating the Earth's age is a fundamental objective of Earth science and only with continued work will the opposing models be fully reconciled with one another. However, at present, the best age of Earth remains ~4.54 b.y.

Luminescence Dating, History

Ludwig Zöller^{a*} and Günther A. Wagner^b

^aGeographisches Institut, Universität Bayreuth, Bayreuth, Germany

^bGeographisches Institut der Universität Heidelberg, Heidelberg, Germany

Definition

Luminescence dating is based on the perception in solid state physics that energy from the absorption of ionizing radiation can be stored in the crystal lattice of insulators as radiation damage. Thermal or optical stimulation of dosed mineral grains results in release of radiation-induced luminescence. The amount of radiation damage and, thus, the acquired luminescence signal is at least within certain limits, proportional to the time during which the insulating minerals were exposed to ionizing radiation. Assuming a constant rate of natural ionizing radiation the age is calculated as the ratio of the accumulated dose over the dose-rate. The present contribution deals with the history of luminescence dating from the first observations of the luminescence phenomenon via the first proposal to use it for dating purposes, and the first dating application to the present wide field of applications in archaeology, Quaternary geology, geomorphology and geoarchaeology.

Early observations of the phenomenon

The term “Luminescenz” was first used in 1888 by the German physicist Eilhardt Wiedemann at the University of Erlangen for “all those phenomena of light which are not solely conditioned by the rise in temperature,” i.e., the condition of incandescence or “hot light” in contrast to luminescence or “cold light” (cited after Harvey 1957). He differentiated various kinds of luminescence according to the method of excitation or of stimulation, such as photoluminescence, thermoluminescence, triboluminescence and chemiluminescence. When irradiating various minerals with “Entladungsstrahlung” (cathode rays) Wiedemann and his colleague Gerhart Schmidt (Wiedemann and Schmidt 1895) observed, after gentle heating, a light-emission and thus first described the phenomenon of “thermoluminescence” (TL), which is a thermally stimulated radioluminescence induced by ionizing radiation. Experiments with the phenomenon of luminescence led in the same year to the epochal discoveries of X-rays by Conrad Roentgen at Würzburg and of the natural radioactivity by Henri Becquerel at Paris only 1 year later.

Actually, a luminescence phenomenon had been already scientifically described more than 200 years before by Robert Boyle. He reported on 28 October 1663 to the Royal Society “About a diamond that Shines in the Dark” and adding experimental details, particularly “I also brought it to some kind of Glimmering Light, by taking into bed with me, and holding it to a good while upon a warm part of my Naked Body” (cited after Aitken 1985). A few years later Johann Sigismund Elsholtz (1676) at Berlin described a similar property for the mineral fluorspar. There are also much

*Email: ludwig.zoeller@uni-bayreuth.de

earlier reports on luminescent gems and stones which glimmer in the dark after being exposed to light, probably a kind of photoluminescence (Harvey 1957).

Evolution of TL dating: from first suggestions to first results

It was Farrington Daniels and coworkers at the University of Wisconsin in 1953, while measuring exposure of minerals to nuclear radiation, who first proposed to use thermoluminescence also for geological and archaeological age determination (Daniels et al. 1953). Ceramics and burned bricks, mainly from the Roman period, were the first archaeological materials on which the suggested method was successfully tested by Norbert Grögler and colleagues at the University of Bern (Grögler et al. 1958, 1960), followed by Kennedy and Knopff (1960) at the University of California. Starting from this point, luminescence dating gradually evolved into a powerful tool for heated archaeological materials. This was mainly due to the efforts by Martin Aitken and his team at the University of Oxford during the 1960s (Aitken et al. 1964, 1968b, cited after Aitken 1985), but gradually also other laboratories became involved. The essential procedures of pottery TL-dating were developed: the quartz inclusion technique (Fleming 1966) and the fine-grain technique (Zimmerman 1967). An important by-product of these methodological developments was the TL authenticity-testing of ceramic objects (Fleming et al. 1970). In addition to baked clay, TL dating has been also applied to heated stones, in particular to flint artefacts (Göksu et al. 1974).

Dating of Sediments

With the recognition that not only heating, but also optical bleaching resets the TL signal (Wintle and Huntley 1979), the method became also applicable to the dating of sediments. The observation made on quartz that intense green illumination, instead of heating, also stimulates luminescence (Huntley et al. 1985) opened the door for utilizing the phenomenon of Optically Stimulated Luminescence (OSL) for dating. Soon afterwards the luminescence stimulation by infrared illumination of feldspar was discovered (Hütt et al. 1988).

TL Dating of Sediments

The observation that the natural TL intensities from Quaternary sediments increase with geological age stimulated researchers from the former USSR to propose TL as a tool for the chronology of sediments. Pioneer research was done by V. N. Shelkopyas and G. V. Morozov at Kyiv (Dreimanis et al. 1978). The lack of English publications by the Kyiv group makes it difficult to fully understand sample preparation and measurement protocols. The apparently most important early work is noted in Morozow (1968) and Shelkopyas and Morozow (1981) even if a first note by Shelkopyas and Morozow (1965) dates a few years earlier. Favourable material for the Kyiv group was loess from which they first tried to establish a relative TL chronology by a kind of regeneration of the natural signal using X-rays or γ -irradiation. Later, numerical ages were calculated assuming that almost all relevant natural growth of the TL signal was due to natural alpha irradiation but this idea was revised by Shelkopyas and Morozow (1981) accounting for an alpha efficiency of ca. 0.1. A fully reliable TL dosimetry satisfying modern requirements (e.g., Aitken 1985; Guerin et al.

2011) was not delivered in the early work at Kyiv. But also the estimation of the equivalent dose ED remained questionable. Thus, Wintle and Huntley (1982) doubted the reliability of these TL ages.

Despite this, several merits of the early work at Kyiv and some technical details deserve mention. The heating rate was only 1 K/s up to 300 °C or 350 °C. Photomultipliers of the Russian type FEU-19 and FEU-29 with maximum sensitivity at ca. 380 nm were used for detection. The peak of the natural TL was found at ca. 230 °C hotplate temperature. Despite the lack of rigorous physical and chemical mineral separation the Kyiv group dubiously stated that the TL signal was obtained from quartz grains. Experiments using coarse (1 mm) as well as small ground “quartz” grains (0.01 mm) showed much smaller TL from fine grains. Although resetting of the TL signal by UV light was also observed, Morozow (1968) concluded that triboluminescence due to weathering and transport was the main factor to reset the inherited TL signal. Wintle and Huntley (1979, 1980) first demonstrated that sunlight exposure bleaches the TL signal of sediments which, however, does not rule out the effect of triboluminescence.

Clearly, the merits of the early work done in Kyiv are to have shown the capability of TL from sediments to establish a relative and stratigraphically consistent chronology from Quaternary sediments. For details of further development of TL sediment dating we refer to Wintle and Huntley (1982).

The work by Wintle and Huntley (1979, 1980) boosted the development of TL dating for sediments. Since daylight bleaching was identified as the main resetting mechanism further work concentrated on TL dating of wind-lain sediments, in particular loess and dune sands. But also fluvial and coastal sediments were tested. Special attention was directed to determine the unbleached residual of the TL at deposition to circumvent age overestimates. The originally applied “R-Γ” respectively “R-β”-method (Wintle and Huntley 1980) was complemented by additive and regenerative “total bleach” methods for aeolian sediments of middle and lower latitudes for which a resetting of the TL at deposition to an unbleachable residual was assumed. Further “partial bleach” methods to account for partial resetting at deposition were proposed by Mejdahl (1985). Meanwhile refined techniques for TL dosimetry allowing for calculation of more accurate and reliable effective dose-rates (e.g., Aitken 1985; Mejdahl 1979) contributed further steps towards meaningful TL ages of sediments. The “feldspar inclusion technique” (Mejdahl 1983) was extended to dating of sediments and, thus, advantage was taken from dating of different mineral phases with different TL characteristics.

The euphoria at the early 1980s was dampened beginning in 1985 when significant TL age underestimates from loess older than 30–100 ka (1,000 years ago) became obvious from many publications. The poorly understood phenomenon of “anomalous fading” from feldspars was often made responsible for this, but some authors claimed that reliable ages up to 300 ka or even 800 ka could be obtained (e.g., Singhvi et al. 1989; Berger et al. 1992). To some extent, non-standardized laboratory protocols contributed to the uncertainty. Zöller et al. (1988, 1991) demonstrated that the reliable TL age range from loess could be extended to a minimum of about 100 ka. Besides the “effective mean lifetime” τ of an electron trap (c.f. Wagner 1998), “dose-dependent sensitivity change” (Wintle 1985) was suggested to explain observed age underestimates from older loess. Finally, efforts were made to additionally investigate the characteristics and stability of luminescence centres using a CCD camera-based luminescence spectrometer (Rieser et al. 1994).

On the other hand, the risk of TL age overestimates from sediments due to incomplete optical resetting (often referred to as incomplete bleaching) at deposition gave increasing distinction to the discussion. This resulted in the development of OSL dating (Huntley et al. 1985; Hütt et al. 1988; Aitken 1998). Finally, the TL dating of sediments was almost completely abandoned since the mid-

1990s. Some laboratories, however, have continued with TL dating of loess and have published reasonable results even for loess >200 ka (Kuziak et al. 2007).

Recent developments of TL dating

TL dating of burned flint as direct dating of ancient human activity has been an important application since 1974 (Göksu et al. 1974). Recent developments, including microdosimetry problems of some flint tools, are described in Richter (this volume). Successful TL dating results for volcanic eruptions using quartz, feldspars or volcanic glass are reviewed by Fattahi and Stokes (2003). The more recent availability of band-pass filter glasses for detecting luminescence emissions in a narrow wave-length band has resulted in the intensified use of orange-red emissions (ca. 620 nm) from quartz. Despite the disadvantage of a much lower signal/noise ration the great advantage of the 620 nm emission from quartz is its high saturation dose which exceeds the saturation dose of UV-A (315–400 nm wavelength) or blue emissions by more than an order of magnitude. Meaningful TL ages >1 Ma using the orange-red emission from quartz appear obtainable (Fattahi and Stokes 2000). As volcanic quartz is not a significant component in most mafic rocks, Zöller and Blanchard (2009) used heated crustal xenoliths and maar tephra for TL dating, but different techniques yielded diverging ages so far, which points to pending problems. TL dating of baked loess from a Lower Gravettian hearth in Austria, however, resulted in congruent ages obtained from blue TL emission of polymineral fine grains and orange-red emissions from quartz separates in agreement with results from independent dating methods (Zöller et al. 2013). Aeolian quartz grains baked by lava flows were successfully dated to ca. 170 ka using orange-red TL emissions (Suchodoletz et al. 2012).

Surface Dating

In addition to sediment dating, it is also possible to determine the age when the surface of a stony object, which had been exposed to daylight before, became ultimately shielded from light. This allows dating various archaeological and geological events, such as the construction as well as the destruction of stone buildings, the burial of stone artefacts and the sedimentary deposition of boulders. Liritzis (1994) proposed to use TL to date the construction of a megalithic limestone building. But the applied methodology was hampered by the fact that in calcite – even after extended exposure to sunlight – retains a significant residual TL signal (Liritzis and Galloway 1999). As in sediment dating, this problem of unbleachable luminescence signals is overcome by the use of OSL instead of TL. It seems, therefore, consequent to employ OSL dating also to stone surfaces. Early attempts to determine the burial age of quartzite pebbles by this approach were reported by Huntley and Richards (1997). After scraping off the uppermost part from the bleached surface of lithic artefacts, IRSL dating was applied to the fine-grained feldspar fraction, whereby uncertainties with insufficiently bleached grains were encountered (Morgenstein et al. 2003). When utilizing a high spatial resolution OSL-detection technique (HR-OSL) of minerals that are left in their original petrologic context, i.e., without any mineral separation, Greilich et al. successfully dated a stonewall of the medieval castle of Lindenfels, Germany, and the pre-Columbian Nasca lines (geoglyphs) around Palpa in southern Peru (Greilich et al. 2002, 2005).

Perspectives of TL Dating

The appropriate method for age determination of sediments is presently optical dating, in particular for young sediments. The upper age limit of optical dating is, despite more recent attempts using post-IR-IRSL (pIR-IRSL) or Thermal Transfer-OSL (TT-OSL) dating, hampered by either low saturation doses or by age underestimates. As for older sediments the unbleached TL residual becomes increasingly negligible, TL dating protocols deserve further attention. The more promising application of TL dating will, however, be concentrated on heated materials such as artefacts or rocks heated by, e.g., volcanic eruptions.

Recent developments of OSL and IRSL dating

As IRSL and, in particular, OSL minimizes the problem of age overestimates due to unbleached residuals at deposition, the rapid development of OSL dating enabled the assessment of reliable chronologies of sediments from Late Glacial and Holocene and of archaeosediments. The Single Aliquot-Regeneration (SAR) protocol (Murray and Wintle 2000) became soon established as a routine protocol. High resolution deciphering of landscape development under the influence of mankind not only supplied chronostratigraphies of geoarchaeological sites but also initiated further development and verification of geomorphologic and geoarchaeologic concepts (e.g., Lang and Hönscheid 1999; Lang et al. 1999; Fuchs et al. 2004).

The very rapid bleaching of quartz-OSL and the application of statistical methods to discriminate between well and poorly bleached sub-samples measured by the SAR protocol opened up the ability to obtain meaningful dating results from sediments or geomorphologic events not datable by luminescence before, such as periglacial slope deposits (Hülle et al. 2009) or tsunamites (Brill et al. 2012). The rather low saturation dose of quartz-OSL, however, limits the upper dating range to less than or around 100 ka, depending on the natural radioactivity of the sediment. The much higher saturation dose of feldspar-IRSL may allow for an upper dating limit of 200–300 ka or even more, but the limiting factor was found in the phenomenon of “anomalous fading,” an athermal long term instability of the luminescence from feldspars first described by Wintle (1973). Procedures to correct for anomalous fading were proposed by Huntley and Lamothé (2001) and Auclair et al. (2003) but they are expected to yield reliable results only in the linear part of the dose–response curve. More recently, the “post IR-IRSL” (pIR-IR) protocol was developed and tested (Buylaert et al. 2009, 2012; Thiel et al. 2011; Murray et al. 2013). It was found that the fading of the pIR-IR signal is significantly lower allowing reasonable age estimates of a few hundred ka. To extend the dating limit of quartz OSL by an order of magnitude a “Thermal Transfer-OSL” (TT-OSL) protocol using recuperated OSL was suggested (Wang et al. 2006, 2007; Porat et al. 2009) but results from testing the protocol still appear ambiguous (e.g., Zander and Hilgers 2013).

Perspectives of OSL and IRSL Dating

On the one hand, the new methodological developments of OSL dating as well as technical improvements of the luminescence readers enable dating of sediments deposited as young as a few years or decades. Thus, luminescence dating is ready for bridging the gap between historical geology (dating of past events) and process geomorphology (estimation of recent process rates). On

the other hand, the extension of the dating range beyond 100 ka towards 1 Ma remains a challenge, but first promising steps are breaking new ground.

OSL dating of rock surfaces (i.e., last exposure to daylight) is expected to gain increasing relevance for archaeology and geomorphology, in particular since the latest developments of commercial luminescence readers provide the option of spatially resolved luminescence measurements.

Infra-Red Radiofluorescence Dating

Although the infrared radiofluorescence (IR-RF) technique follows the same basic principles as TL and OSL dating, its dose determination differs from them. The underlying phenomenon is unequivocally a fluorescence effect (Krbetschek et al. 2000), and thus the original name was later changed from “radioluminescence” to “radiofluorescence” (Erfurt and Krbetschek 2003). IR refers to the near infrared emission (865 nm), which is characteristic for potassium feldspars, such as microcline and orthoclase. The physical background and radiation-dose dependence of this phenomenon have been intensively investigated, along with the methodological aspects of dating Quaternary sediments (Degering and Krbetschek 2007). Of particular interest for the data presented is the long-term stability of the IR-RF signal. It is possible to obtain IR-RF ages in agreement with independent age controls back to ~700 ka, such as demonstrated for the type-site of *Homo heidelbergensis* at Mauer, Germany (Wagner et al. 2010).

Further Reading

Further reading is recommended: Duller (2008), Preusser et al. (2008), Roberts (2008), and Wintle (2008). Periodicals informing about latest progress in luminescence dating are mainly *Ancient TL*, *Archaeometry*, *Quaternary Geochronology* and *Radiation Measurements*. Proceedings of the triennial international conference on Luminescence and ESR Dating (LED) are published in special volumes of *Quaternary Geochronology* and *Radiation Measurements*.

Summary

Within the last ca. 50 years the development of luminescence dating has been fast-paced. Originally, thermal stimulation (TL) was applied to date ceramics and heated artefacts. Later, the recognition of solar resetting of the luminescence signal broadened the application of luminescence dating strongly in a sustainable matter. For the first time, the sedimentation age of Quaternary sediments could be dated directly, first by TL and then later by optical stimulation (OSL). Beyond archaeology, luminescence dating has developed to become an indispensable scientific tool in Quaternary geology, geomorphology, and geoarchaeology world-wide. Challenges for ongoing research appear to focus on extension of the dating range towards the more recent as well towards older dating limits.

Magnetic Chronology

Manuel Calvo-Rathert*

Departamento de Física, Escuela Politécnica Superior, Universidad de Burgos, Avenida de Cantabria s/n, Burgos, Spain

Definition

Study of the variations with time of the Earth's magnetic field by the analysis of direction and intensity of magnetization recorded by rocks, sediments, and archaeological materials and its use for dating and chronological correlation purposes.

Variations of the Earth's Magnetic Field

The present-day magnetic field at the surface of the Earth can be well approximated by an inclined magnetic dipole placed at the Earth's center which forms an angle of $\sim 11.5^\circ$ with the rotation axis. Such a dipole accounts for nearly 90 % of the field at the Earth's surface. The still significant amount remaining can be described by the non-dipole field. The Earth's magnetic field (EMF) is, however, not static, as its direction and strength vary with time. This field variability spans time scales ranging from fractions of a second to millions of years. The short-term variations arise mostly from currents flowing in the ionosphere and magnetosphere. The slower changes are produced by the so-called main field, which is generated by magnetohydrodynamic processes in the Earth's liquid iron outer core, and display periods of a year to millions of years. Periods of internal origin of an order shorter than a year cannot be detected at the Earth's surface because of the screening effect of the lowermost mantle (e.g., Merrill et al. 1998). Since a magnetic field has existed on the Earth since early in its history (e.g., Tarduno et al. 2010) and its direction and intensity vary with time with a broad spectrum of frequencies, it can be used as a dating tool on very different time ranges.

According to their magnitude, length, and global or regional character, different types of variations of the EMF can be distinguished. Variations of both direction and magnitude with periods ranging between years and tens of thousands of years are termed secular variation (SV). SV can be described as produced by the combined effect of variations in the dipole field and changes in the strength and location of the non-dipole field components. The former are synchronous on a global scale and are characterized by longer periods, while the latter vary over smaller distances and display shorter periods. As a result, patterns of SV are similar over subcontinental regions but differ markedly between continents.

Besides secular variation, one of the main characteristics of the EMF is that it switches its polarity, interchanging the positions of magnetic north and south. The duration of geomagnetic polarity intervals is rather variable, ranging between some tens of thousands and several millions of years. The term polarity chrons is used for the main subdivisions of time recognized on the basis of polarity, while short (0.1 Ma) polarity intervals occurring within a chron are termed subchrons (Harland et al. 1990). Periods of stable polarity are interrupted in several occasions by short-lived geomagnetic "events" of a few thousands of years of duration (e.g., Laj and Channell 2007) called excursions.

Paleomagnetism

Detailed records of geomagnetic secular variation are only available for the last 400 years (Jackson et al. 2000), but there are no direct surviving observations of the EMF prior to this period of historical observations. Thus, information about characteristics and variations of the ancient geomagnetic field has to be obtained indirectly. Both rocks and archaeological materials can carry a remanent magnetization that is in most cases parallel to the field in which they were magnetized, so that its measurement can supply the direction of the EMF vector in the past. The determination of the ancient magnetic field by studying the magnetization recorded in rocks or other materials led to the development of paleomagnetism (e.g., Butler 1992; Tauxe 2010, which are good introductory books on this subject).

Rocks (or archaeological materials like ceramics or bricks) are assemblages in which fine-grained ferromagnetic minerals are dispersed within a matrix of diamagnetic and paramagnetic minerals. The stability of remanent magnetization is largely dependent on the grain size of these ferromagnetic minerals. Thermal oscillation leads to magnetic relaxation, in which remanent magnetization of an assemblage of grains decays with time. The most stable magnetization occurs in particles with single-domain (SD) state, characterized by a uniform magnetization. Less stable magnetization is carried by larger particles which are not uniformly magnetized and are referred to as multidomain (MD) grains. Very small uniformly magnetized ferromagnetic grains are, however, in a superparamagnetic state and are only able to produce a rapidly decaying short-lived remanent magnetization. On the other hand, remanent magnetization carried by SD grains can remain stable without decaying for time spans of the order of magnitude of the age of the Earth.

There are different mechanisms leading to the acquisition of a remanent magnetization. A thermoremanent magnetization (TRM) is acquired when a material is cooled down from above its Curie temperature in the presence of a magnetic field. The Curie temperature is a temperature characteristic of each ferromagnetic mineral type above which it loses its ability to preserve a remanent magnetization. A TRM is parallel to the ambient geomagnetic field direction during remanence acquisition and is typically found in igneous rocks or archaeological materials which have been subjected to firing (e.g., pottery, bricks, or kilns).

A detrital remanent magnetization (DRM) is acquired during deposition of sedimentary rocks. During deposition in a quiet environment, magnetized particles that can rotate freely will turn into the direction of the applied geomagnetic field like compass needles and will be subsequently locked in place during lithification. The formation of sedimentary rocks is, however, rather complex, and remanence acquisition may be affected by a variety of conditions and processes, like a diversity of initial mineralogies, perturbations during sediment deposition, Brownian motion of magnetized particles, flattening into the bedding plane by compaction, post-depositional modification through the action of organisms, or diagenesis. A remanent magnetization acquired due to physical alignment processes after deposition but before consolidation is usually termed post-depositional remanent magnetization (pDRM).

Relaxation time of small superparamagnetic grains can be dramatically increased by augmenting their grain size. Chemical changes that form ferromagnetic minerals which grow large enough in a magnetizing field create a chemical remanent magnetization (CRM) if this chemical changes take place at temperatures not as high as to produce a TRM. Chemical reactions giving rise to new ferromagnetic minerals include the alteration to a ferromagnetic mineral of a preexisting one and the precipitation of a ferromagnetic mineral from a solution. Very often CRM is a secondary magnetization, not acquired during rock formation but long after.

Paleointensity

Although in many paleomagnetic studies only directional information about the geomagnetic field is needed, its intensity also contains valuable information concerning field variability. Therefore, several investigations also demand the knowledge of the strength of the paleofield vector, which is called the paleointensity. Its determination is more difficult, since the magnitude of the paleofield vector cannot be directly read from the magnetization vector. While the direction of magnetization is, in most cases, parallel to the direction of the applied field, its magnitude is only proportional to the field intensity and only if the latter is low, like in the case of the geomagnetic field. In order to retrieve the strength of the magnetizing field, experiments which try to duplicate the acquisition of remanent magnetization in a known field have to be carried out. Complex remanence acquisition mechanisms like the ones creating CRM or DRM are, however, almost impossible to reproduce exactly in laboratory experiments. TRM acquisition, on the other hand, is easier to reproduce in laboratory experiments and well supported by a theoretical basis (Néel 1949; 1955). If a TRM_a was acquired by a rock in an ancient geomagnetic field B_a , TRM_a should be proportional to B_a . In the laboratory, a new TRM_{lab} can be imparted to the rock in a known field B_{lab} . If the proportionality constant between magnetizing field and magnetization is in both cases the same, the strength of the ancient geomagnetic field $B_a = B_{\text{lab}}(\text{TRM}_a/\text{TRM}_{\text{lab}})$. This experimental procedure is the foundation of the initial and most reliable technique for absolute paleointensity determination (Thellier and Thellier 1959). Fired archaeological materials and volcanic rocks should be therefore most suitable to determine absolute paleointensity.

DRM or pDRM acquisition is a complex process that cannot be reproduced exactly in laboratory experiments. Non-field effects like mineralogy and amount or magnetic domain state of the ferromagnetic materials present in a sedimentary sample must be removed from the magnetization signal in order to isolate the dependence of DRM on the ancient geomagnetic field intensity. Typically, the intensity of the remanent magnetization of a sample is divided by a factor that is sensitive to the amount of remanence-carrying grains present in the sample, like magnetic susceptibility or specific laboratory-induced remanence types. The normalized DRM or pDRM obtained this way will at best reflect the relative intensity of the applied geomagnetic field and is termed relative paleointensity. Results from globally distributed records allowed the construction of weighted averages of many relative paleointensity records which can be used as dating and millennial-scale correlation tools (e.g., Guyodo and Valet 1999), and ongoing studies are extending paleointensity stacks further back in time (e.g., Valet et al. 2005).

Magnetic Chronology

Time variations of the EMF take place in a wide range of periodicities, and the determination of polarities, directions, and intensities of remanent magnetization in paleomagnetic and paleointensity studies can be used as a powerful chronological tool. Magnetic chronology methods and techniques differ, however, according to the age and thus the time resolution needed.

Geomagnetic Polarity Reversals

One of the main characteristics of the Earth's magnetic field is that it has reversed its polarity many hundreds of times. A polarity reversal is a global event, experienced simultaneously all over the Earth. Thus, geomagnetic reversals provide a convenient means of stratigraphic correlation and dating. The correlation of polarity intervals with biostratigraphic stage boundaries associated to

radiometric ages yields a dated geomagnetic polarity time scale (GPTS) (Fig. 1). The development of the GPTS was initiated in the 1960s combining polarity data from globally distributed Pliocene-Pleistocene igneous rocks with ages obtained from the newly developed potassium-argon (K–Ar) dating method (e.g., Cox et al. 1964). The precision of the radiometric dating put, however, a practical limit to the application of this technique, as the error in determining the age of a lava sample that is about 5 Ma old was longer than the duration of many short events. The paleomagnetic study of deep-sea cores, in which sedimentary horizons could be paleontologically dated, allowed extending the polarity time scale into the Miocene (e.g., Opdyke et al. 1974). More recently, stratigraphic sequences have also been dated using climatically induced changes in lithology or stable isotopic records in sediments that are caused by variations in the Earth's orbit around the sun. This method is known as astrochronology, and astronomical tuning has allowed for a much more detailed and accurate chronology for the younger Cenozoic polarity reversals (Shackleton et al. 1990).

Seafloor spreading has created sequences of lineated marine magnetic anomalies in the ocean basins which provide the most complete and detailed record of geomagnetic polarity in the time interval between Middle Jurassic – the oldest seafloor – and present. Investigations of magnetic anomalies in all major oceanic areas yield a clear, consistent record of the history of geomagnetic polarity during the past 155–160 Ma. (e.g., Lowrie 2007a, b and references therein; Fig. 1). Because the age of the oldest seafloor is about 180 Ma and magnetic anomalies in these areas display subdued amplitudes, early polarity intervals have to be verified using magnetostratigraphic sections obtained from land exposures (e.g., Channell et al. 1995). Knowledge of geomagnetic polarity history older than late Jurassic is, however, still irregular.

The GPTS is a useful tool for dating stratigraphic sequences. By measuring the magnetization recorded in samples from a section and correlating the obtained polarity pattern to the GPTS, a precise temporal framework for the studied sequence can be obtained. This procedure is called

Fig. 1 Geomagnetic polarity time scale with magnetic anomaly numbers for the past 160 Myr (Figure from Merrill et al. 1998)

magnetostratigraphy (e.g., Opdyke and Channell 1996), and it allows correlating stratigraphic information on a global basis. Although the number of polarity reversals occurred during the Quaternary is small, their study has also been useful by providing a temporal reference in studies concerning hominin presence (e.g., Parés and Pérez-González 1995; Calvo-Rathert et al. 2008).

Geomagnetic Excursions

Recognition of brief polarity excursions as a part of the Earth's paleomagnetic field behavior has developed during the last two decades together with astrochronological calibration of the polarity time scale. During this time, numerous geomagnetic excursions have been discovered in the previously believed stable last two chrons, Brunhes and Matuyama (e.g., Laj and Channell 2007), although their number is still a matter of debate. Singer et al. (2002) propose the development of a geomagnetic instability time scale (GITS) for the Brunhes and late Matuyama chrons (Fig. 2).

Although theoretically geomagnetic excursions could be a useful correlation and dating tool in Quaternary stratigraphy, their utilization can be rather problematical. Questions like if they are local or global in extent or if they are mainly due to dipolar or non-dipolar field variations (e.g., Roberts 2008) can impose severe limitations to their applicability to chronological purposes. Merrill and McFadden (2005) recommend the use of excursions as a correlation tool only for locations separated

Fig. 2 The geomagnetic instability time scale (*GITS*) for the Brunhes chron. Column at *left* shows the relative paleointensity SINT-2000 stack (Valet et al. 2005). Ages in the *GITS* are from $^{40}\text{Ar}/^{39}\text{Ar}$ dated lava flows and astrochronologically dated Ocean Drilling Project (ODP) cores (Singer et al. 2014 and references therein, figure modified from Singer et al. 2014)

less than 30° on the Earth's surface, as they are not global field features. On the other hand, as features of the geomagnetic field like the Laschamp or Iceland Basin excursions represent full polarity reversals and all adequately defined excursions are characterized by a decrease in intensity (e.g., Laj and Channell 2007), they can be valuable in Quaternary geochronology if used with caution. Nevertheless, their short duration (less than 5 ky, e.g., Laj and Channell 2007) also imposes limitations to their applicability to chronological purposes, as they can be filtered out of sedimentary records (Merril and McFadden 2005).

Archaeomagnetism and Paleosecular Variation

The study of the magnetization found in archaeological objects – and mainly of the TRM recorded in materials which have undergone firing at the time of their fabrication or use – is called archaeomagnetism. Retrieval of the direction of magnetization requires that the studied objects are in situ or their original position is known. Other artifacts may have been fired in an unknown position and only their paleointensity (called archaeointensity) can be determined. Also lava flows whose age is known from historical records can be used for archaeomagnetic studies. When the age of the object or its last firing is known – by methods such as radiocarbon dating, thermoluminescence, and the use of historical records – the archaeomagnetic and archaeointensity data obtained can be incorporated into a master curve for the region where the remanence was acquired (Fig. 3). The establishment of regional archaeomagnetic records needs that individual determinations from

Fig. 3 Secular variation curve for Iberia obtained by Bayesian modeling of data coming from localities less than 900 km from Madrid: (a) stereoplot of declination and inclination, where orange and red indicate century time scales. A thin line indicates curve sectors based on a small number of data, (b) declination versus time, and (c) inclination versus time (Figure from Gómez-Paccard et al. 2006, this figure is reproduced with permission of John Wiley & Sons, Inc.)

different locations are reduced to a common one, following the approximation that the geomagnetic field is described by a tilted dipole (Noël and Batt 1990). Due to the importance of non-dipole field components in secular variation, master curves for directional studies can be only constructed for areas of subcontinental size, of not more than about 1,000 km radius. Spatial variations in intensity are usually modeled using an axial geocentric dipole model of the geomagnetic field. Archaeomagnetic dating is performed by comparing directional and intensity data of an archaeological artifact of unknown age with a reference curve (Fig. 3).

Secular variation that predates magnetic observatories is often referred to as paleosecular variation (PSV). The most suitable material for PSV studies are sediments which can provide a high resolution and a good continuity, like oceanic sediments of continental margins or lake sediments. In PSV studies in lakes, several cores are usually obtained and correlated using physical characteristics of the sediments like magnetic susceptibility or other lithological markers. Age control is provided by varve counting, isotopic dating on organic material, palynology, and identification of tephra levels. Regional declination, inclination, and intensity of PSV master curves can be obtained by stacking of PSV records of several lakes of the same region (e.g., Snowball et al. 2007).

Several global models using spherical harmonic analysis have been constructed using archaeomagnetic data, lava flows, and lake sediment records as input data during the last decade (e.g., Korte and Constable 2009). Specific regional models of secular variation have been developed from archaeomagnetic and sedimentary data, which are fitted to series of mathematical functions (e.g., Pavón-Carrasco et al. 2010). This kind of models allows determining a secular variation curve for a chosen location within the study region.

Magnetic Paleointensity Stratigraphy

The dominantly dipolar nature of geomagnetic paleointensity variations provides a global signal not only during polarity reversals but also within periods of stable polarity. This signal can be used to supply a high-resolution (millennial-scale) time scale for Quaternary chronostratigraphy (e.g., Roberts et al. 2013). Sedimentary sequences allow obtaining continuous records of relative geomagnetic paleointensity variations (Fig. 2). Detailed relative paleointensity stacks now span the entire Quaternary, and some records or stacks of records from rapidly deposited sediments provide millennial-scale chronological resolution (e.g., Roberts et al. 2013 and references therein). Recognition that precisely dated, detailed paleointensity records are coherent on a global scale is leading to the use of relative paleointensity as a means to constrain the chronology of a sedimentary sequence, often termed paleointensity-assisted chronology (e.g., Roberts et al. 2013).

Summary

Direction and strength of the Earth's magnetic field vary with time. The changes produced by the main field, which is generated by magnetohydrodynamic processes in the Earth's liquid iron outer core, display periods of the order of a year to millions of years. Analysis of the remanent magnetization recorded by rocks, sediments, and archaeological materials allows retrieving direction and intensity of the ancient magnetic field which produced the remanence.

In order to be useful as a dating tool, the changes of direction and intensity of the EMF both with time and with location – if variations are of regional character – have to be known. If EMF variation reference curves or data have been obtained and dated with other methods (radiometric dating, fossil record, etc.), they can be compared with the polarity, directional, or intensity record of the studied

geological units or archaeological artifacts to be dated. Magnetic chronology methods and techniques differ, however, according to the age and the time resolution needed.

Quartz Defects, Optically Stimulated Luminescence and Thermoluminescence

Marco Martini*

Dipartimento di Scienza dei Materiali and Sezione INFN, Università degli Studi di Milano Bicocca, Milan, Lombardy, Italy

Definition

Point defects in solids. Any break in the regular pattern of a crystal, due to absence of an atom (vacancy) or to an atom of the crystal in a position out of the regular lattice (interstitial) or an extra atom of different species (impurity).

Luminescence. Energy emission in the form of light as a consequence of absorption of energy of various types: As an example radioluminescence occurs when a crystal emits light after absorption of ionizing radiation. As a general rule luminescence involves electrons that increase their energy level in the absorption (excitation) and return to the original level causing light emission (de-excitation).

Delayed luminescence is a particular type of luminescence occurring when on average there is light emission long after the energy absorption. The most frequently reported delayed luminescence is phosphorescence, caused by transition rules that make scarcely probable the radiative recombination.

Thermoluminescence (TL) is a kind of delayed luminescence in a solid. The excited electrons are “trapped” in defect sites. TL is stimulated by increasing the temperature of the emitting crystal, which causes a higher probability of “detrapping” the electrons, allowing them to recombine at luminescence centers, with light emission.

Optically stimulated luminescence (OSL) is another kind of delayed luminescence in a solid, where detrapping of electrons is caused by light stimulation in place of the heating of TL.

Radiation dosimetry. The measurement of the amount of energy absorbed due to the exposition of a material to ionizing radiation. Delayed luminescences, TL and OSL, are appropriate dosimetric techniques.

Electron spin resonance (ESR). Spectrometric technique which detects unpaired electrons in a material. It is also exploited as a dosimetric and dating technique.

Introduction

Quartz is one of the most abundant minerals in the continental crust of the Earth. It is also industrially synthesized to exploit its properties as an electronic oscillator and is present in many electronic devices for high-frequency clocks.

Like all natural and synthetic materials, quartz contains variable concentrations of defects which can have positive and negative effects. In the case of quartz electronic oscillators, the presence of low concentrations of Al ions, which substitute Si ions, produces an unwanted radiation-induced frequency shift, due to the charge-compensating alkali ions at the Al sites. The same Al defects

*Email: marco.martini@mater.unimib.it

together with other defects are responsible for electronic trapping and luminescence recombination that are very useful for dosimetric purposes: based on these properties, radiation dosimetry and ceramics dating are possible.

To correctly deal with these cases, the probability of detrapping must be considered and the phenomenon generally follows an exponential decay and is temperature dependent: at a fixed temperature the intensity of the emitted light exponentially decreases (McKeever 1985; Martini and Meinardi 1997). In most cases luminescence is due to the presence of lattice defects that are generally involved in the recombination of charge following detrapping from defects of higher energy, regardless of the original energy absorption: the emitted wavelengths are very often the same in the various types of luminescence of a certain material. Looking at delayed luminescences, OSL and TL, further defects are to be considered, specifically the ones responsible for charge trapping.

Quartz Defects

The luminescence properties of quartz defects have been the subject of a large number of studies aimed at understanding the complex mechanisms governing the various luminescence emissions and their modifications as a consequence of irradiation and thermal treatments (Preusser et al. 2009; Lieb and Keinonen 2006).

Many defects, both intrinsic and impurity related, are known to be present or produced in quartz, having been identified through various spectroscopic techniques; however so far the role of these defects in producing luminescence emissions is still under discussion. Although a great number of studies have been carried out on the structure properties of defects in quartz, mainly through ESR measurements (Weil 2000), only tentative correlations between defects and luminescence emissions have been put forth. Many defects are known to be present both in the crystalline (quartz) and in the amorphous (silica) forms of SiO_2 , but the luminescence properties of quartz and silica are largely different (Stevens Kalceff and Phillips 1995). Nonetheless there is agreement on the role of some impurity defects in quartz, particularly the so-called Al centers in being related to the emission dynamics (Halliburton et al. 1981; Martini et al. 2012a).

Some intrinsic or impurity-related defects have been proposed as responsible for the luminescence emissions in quartz, while only few proposals of trapping centers are present in the scientific literature so far. It is to be remembered that it happens often that traps and recombination centers are strongly spatially related and some OSL and TL have been proposed to be of this kind (Itoh et al. 2002; Martini et al. 2009).

Two main kinds of quartz defects are reported as related to its luminescence properties: oxygen vacancies, the most frequently occurring intrinsic defects, and Al centers, an ubiquitous type of impurity center. Besides these defects, other impurities, like Ti, Fe, and Ge ions, give origin to many defects, and Si vacancies are known to be present as a counterpart to oxygen vacancies; they give origin to H_4O_4 centers, where the presence of H^+ ions balances the Si^{4+} missing charge.

Oxygen Vacancies

The simplest type of O vacancy is the diamagnetic center resulting from the removal of an O atom from the otherwise perfect α -quartz, leaving a direct bond between two Si atoms (Feigl et al. 1974).

This “neutral O vacancy” is often considered as the precursor of the paramagnetic E'_1 center, which can be described as a hole trapped at a neutral O vacancy. The resulting defect features an unpaired electron on one of the two Si atoms, while the other Si ion, being positively charged,

Fig. 1 Intrinsic defect centers in quartz (Taken from Preusser et al. 2009)

moves away from the vacancy into a nearby plane configuration (Fig. 1) (Rudra and Fowler 1987). The neutral O vacancy capturing a hole is often considered as the most likely precursor of the E'_1 ; however, this relationship is controversial and the precursor of E'_1 is still to be identified.

Besides the E'_1 center, E'_2 and E'_4 are known to be present in quartz as modifications of the E'_1 , being related to the presence of H ions (Fowler et al. 1988). A further group of O deficient centers is the E'' . They are very similar to the E' centers, wherein the number of primes denotes how many unpaired electrons a center possesses. Specifically E''_1 , E''_2 , and E''_3 have been reported, characterized by their slightly different ESR signal (Bossoli et al. 1982). They are all quenched by heating the quartz in the temperature range 50–100 °C.

Al Centers

Al^{3+} ion is the main ubiquitous impurity to which many defects are associated. It is present as a substitutional ion for Si^{4+} and is charge compensated by an alkali ion (M^+) or by an H^+ ion, giving rise to $[AlO_4/M^+]^0$, $[AlO_4/H^+]^0$, respectively. When neither M^+ nor H^+ is present near a substitutional Al^{3+} ion, this latter can be charge compensated by a positive hole, giving rise to the $[AlO_4]^0$ center (Halliburton et al. 1981). The three kinds of Al centers and their interrelations are shown in Fig. 2.

Quartz Luminescence, TL and OSL

Many useful results on quartz luminescence come not only from TL and OSL, but also following other types of stimulation, mainly cathode- and radioluminescence. In these cases trapping is not considered and only luminescence centers are investigated.

Three main emissions are known to be present in quartz luminescence: a UV luminescence reported at 330–380 nm; a blue luminescence, generally reported at around 470 nm; and a red luminescence at around 620 nm. It must be noted that the listed emissions (UV, blue and red) are probably composite. This would explain why each of them is often reported at different wavelengths. The blue emission has been shown to be due to the sum of a band at 485 nm (2.53 eV) and

Fig. 2 Al centers in quartz (Taken from Preusser et al. 2009)

a band at 435 nm (2.85 eV). In radioluminescence spectra the first is enhanced by irradiation and the second is quenched by it (Martini et al. 2012b).

A typical TL glow curve of quartz is given by three main glow peaks at around the following temperatures (using a 20°C/s heating rate): 110°C , 220°C , and $325\text{--}375^\circ\text{C}$. The emission wavelength at a given temperature can vary among different types of quartz, but also in some cases different glow peaks in the same specimen emit at the same wavelength.

The 110°C TL peak in an untreated quartz emits in the blue, but after repeated room temperature (RT) irradiation, followed by heating to temperatures in the range $350\text{--}450^\circ\text{C}$, the sensitivity of the quartz crystal greatly increases, even of orders of magnitude: this is the phenomenon known as “pre-dose effect.” Zimmerman (1971) interpreted the increased intensity as the result of an increase in activated luminescence center concentration. It is to be noted that the 110°C TL emission of

Fig. 3 (a) Sequence of radioluminescence spectra of a natural quartz during irradiation (each spectrum after a dose of 20 Gy), followed by a heating up to 500 °C. (b) Sequence of thermoluminescence glow curves of a natural quartz after irradiation (each spectrum relative to a dose of 20 Gy), followed by a heating up to 500 °C, like in (a). (c) Dose response curve of the 360 nm (3.43 eV) radioluminescence emission band and of the 110 °C thermoluminescence glow peak. The data are normalized to the final value (Taken from Martini et al. 2012b)

a “pre-dosed” quartz is in the UV, at 360 nm; see Fig. 3 (Martini et al. 2012b). OSL emits in the UV as well (Huntley et al. 1996; Martini and Galli 2007), and this was supported by evidence of a pre-dose effect for the OSL signal (Stoneham and Stokes 1991; Koul and Chougankar 2007).

OSL, as well as TL, is also seen to greatly enhance its sensitivity as a consequence of high temperature annealing (Poolton et al. 2000; Schilles et al. 2001; Chen et al. 2001; Lai et al. 2008). This effect is proposed to be related to the variation of concentration of E’₁ centers that may act as non-radiative centers competing in the recombination process (Poolton et al. 2000).

The emission wavelength of the main dosimetric TL peak at 375 °C is strongly dependent on the origin of quartz: some quartzes have a dominant blue emissions, others emit in the red (Shimizu et al. 2006).

It is to be noted that the most commonly used filters to detect TL are centered at around 400 nm, with high efficiency for detecting the blue emissions at about 470 nm, while the red TL at about 640 nm is effectively excluded.

In most quartz a further glow peak is seen at 325 °C. This glow peak has been related to the 110 °C glow peak and to OSL (Kaylor et al. 1995; Wintle and Murray 1997). It has been seen to have the same emission as the OSL and the 110 °C peak, in the range 380–420 nm.

Recombination Models

So far it is not possible to definitely assign each emission to a specific center; however some proposals find a good deal of support. There is agreement on the fundamental role of Al centers in participating in the luminescence of quartz. In untreated quartz, Al is known to be present mainly as charge compensated by an alkali ion, generally Li^+ . Irradiation detaches Li^+ which is then free to move along the channels parallel to the crystallographic c-axis. The effect is the transformation of $[\text{AlO}_4/\text{Li}^+]^0$ to $[\text{AlO}_4/\text{H}^+]^0$ or to $[\text{AlO}_4]^0$ centers, depending on how many H^+ ions are available.

By making specific electro-diffusion treatments (“sweeping”), it is possible to modify the concentration of alkali ions in quartz; if this sweeping is made in air at RT, alkali ions are substituted by H^+ at the Al^{3+} sites. By sweeping out in vacuum at high temperature, Martini et al. (1995) could eliminate from quartz crystals both $[\text{AlO}_4/\text{Li}^+]^0$ and $[\text{AlO}_4/\text{H}^+]^0$, replacing most of them with $[\text{AlO}_4]^0$ centers. They suggested that the 380 nm emission is the result of recombination at $[\text{AlO}_4]^0$ centers, contrary to Yang and McKeever (1990) who related the enhancement of the intensity of the 380 nm emission to changes in ESR active centers, assigning the emission to electron–hole recombination at $[\text{H}_3\text{O}_4]^0$ centers. $[\text{AlO}_4]^0$ has been also proposed as the defect responsible for the blue TL at 470 nm (Woda et al. 2002; Yang and McKeever 1990).

Sweeping turned out to be extremely useful in the study of defects in quartz. Jani et al. (1983) reported a correlation between the growth of the E'_1 center and the decay of the $[\text{AlO}_4]^0$ center and observed that sweeping out the alkali ions strongly reduces the intensity of the E'_1 ESR signal. Poolton et al. (2000) suggested that E'_1 may act as a non-radiative center competing in OSL with the $[\text{AlO}_4]^0$ recombination center.

Quartz Types and Luminescence

Quartzes of different origin present different luminescence emissions: volcanic quartz generally emits in the red (Westway 2009), while slow solidification in plutonic rocks results in strong blue emission (Hashimoto 2008). Hydrothermal quartz also emits at ~480 nm, but the emission has been reported as weak (Rink et al. 1993; Rendell et al. 1994). Shimizu et al. (2006) detected a single emission peak in the red (~630 nm) for a sample of volcanic quartz.

It should be noted however that red emission has been detected in silica, but never in synthetic quartz. Its presence in volcanic quartz could be related to the amorphous inclusions probably present in this kind of natural quartz. Rink et al. (1993) also noticed a large red intensity in volcanic quartz and suggested an assignment to defect clusters.

Conclusions

Many studies on the TL and OSL emissions in quartz provided evidence related to the defects involved in the radiative recombinations, even if definite assignments of each emission to a specific center are still lacking. The main emissions are known to be in the UV (330–380 nm), in the blue at around 470 nm, and in the red at around 620 nm. Precise measurements are clarifying that these emissions are indeed composite, making it more difficult to correctly follow their behavior as a function of irradiation and thermal treatments. As a consequence the assignments proposed so far

are rather tentative, and a systematic definition of luminescence emissions correlated with defect dynamics must be reached as a first step to the assignment-specific roles to defects.

Nonetheless an important and complex role of Al centers in participating in charge recombination can definitely be concluded, but also that migrations by alkali and hydrogen ions promoted by irradiation and/or heating surely play an essential part.

At the same time, the role of oxygen vacancies in indirectly participating in the radiative recombination is clear.

Definitions

Dendrochronology (tree-ring dating): scientific method of dating based on the analysis of patterns of tree rings, also known as growth rings. Dendrochronology can date the time at which gymnosperms and some angiosperms (woody dicotyledonous) were formed tree rings to the exact calendar year.

Surficial processes: processes on the earth surface that shape or have shaped landforms.

Dendrogeomorphology: scientific method to date earth-surface processes in terms of frequency, magnitude, and spatial pattern using the growth-ring series of affected trees.

Introduction

The significant contribution of tree rings to document earth-surface processes lies in their capacity to both preserve evidence of past geomorphic activity and provide critical information on their dating with annual or sub-annual resolution. In many climates, the tree-ring record may represent the most valuable and precise natural archive for the reconstruction and understanding of past and ongoing earth-surface processes during the last several hundred years. As many geomorphic processes are significant natural hazards, understanding their distribution, timing, and controls provides valuable information that can assist in the development of mitigation and defense against these hazards and their effects on society.

This contribution provides an overview of tree-ring-based reconstructions of surficial processes resulting from different geomorphic agents. It outlines the impact of earth-surface processes on tree morphology and wood anatomy and clarifies the approaches used for tree-ring reconstruction of past activity of earth-surface processes. This entry also illustrates the breadth and diverse applications of contemporary dendrogeomorphology and underlines the growing potential to expand these studies, possibly leading to the establishment of a range of techniques and approaches that may become standard practice in the analysis of specific hazards.

What Surficial Processes Can Be Analyzed with Tree Rings?

Dendrogeomorphology has been used in the analysis and reconstruction of a wide range of surficial processes. Some of the earliest applications of dendrochronological research to earth-surface processes utilized roots rather than stem samples to study **erosion processes**. In the 1960s, LaMarche (1968) used tree roots exposed by surface lowering as an indicator of ground surface at the time of germination of 5,000-year-old *Pinus aristata* Engelm. in the White Mountains, California. Corona et al. (2011) focus on areal denudation in marly badlands in the French Alps and illustrate limitations and possible caveats of past approaches using growth rings of roots to reconstruct erosion rates. Stoffel et al. (2012) reconstructed channel wall retreat related to flash floods in the Patagonian Andes of Argentina, and Fantucci (2007) utilized roots to analyze shore erosion in Central Italy.

After the pioneering studies of Hupp (1984) conducted on Mount Shasta (California), tree-ring records were used by Strunk (1991) to reconstruct **debris-flow activity** in the Italian Dolomites. More recently, the frequency and spatial patterns (i.e., lateral spread and extent of flows) have been analyzed in the Swiss Alps (Stoffel et al. 2008; Bollschweiler and Stoffel 2010), including dendrogeomorphic work on frequency-magnitude relations of debris flows (Stoffel 2010) and precipitation thresholds (Schneuwly-Bollschweiler and Stoffel 2012).

Dendrogeomorphic analyses of **landslides** were realized primarily in Canada (Bégin and Fillion 1985) and the French Alps (Braam et al. 1987; Lopez Saez et al. 2013) to document spatial patterns of activity, reactivations, and rainfall patterns triggering landslides. In the first study in the subtropics, Paolini et al. (2005) used suppression-release patterns and inception of *Alnus acuminata* Kunth. trees to date a number of landslides in Argentina.

The occurrence of **snow avalanches** has quite frequently been analyzed with tree rings over the last four decades, beginning with Schaerer's (1972) publication on vegetation in avalanche terrain in British Columbia (Canada). For a long time, tree-ring-based analysis of snow avalanche activity was almost exclusively used in North America (Butler 1979; Germain et al. 2009). Work in the European Alps started in the early 2000s with a focus on runout distances and triggering weather conditions (Stoffel et al. 2006a; Corona et al. 2012).

The analysis of growth rings has also been used in paleohydrology. The first studies linking **fluvial processes** and botanical evidence go back to the 1960s (Sigafos 1964). Later on, a broad array of flood signatures have been defined to date paleofloods (St. George and Nielsen 2000). More recently, scarred trees have been used to estimate flood discharge (Ballesteros et al. 2011) and to analyze flood frequency distributions (Ballesteros et al. 2013).

Surprisingly, and despite the potential of dendrogeomorphic methods, rockfall activity has only rarely been studied with tree rings (Stoffel 2006). The first studies analyzing the seasonality, frequency, and spatial patterns of **rockfalls** using tree rings were only very recently realized by Stoffel et al. (2005) and provided a reliable basis for the analysis of rockfall risks and the accuracy assessment of rockfall models (Stoffel et al. 2006b).

Recent comprehensive discussions of dendroglaciology can be found in Koch (2009). The first, simplest, applications involve determining the inception date of the oldest tree growing on a moraine or other surface to provide a minimum age for the feature or, more rarely, estimates of the rates of glacier recession or succession. In many areas around the world, the glacier advances of the last few centuries were more extensive than earlier Holocene events, and significant dendroglaciological work has been done using recently exposed stumps or logs in glacier forefields to estimate the dates of earlier events or ice-free periods, providing the tree-ring records can be cross-dated against reference chronologies. However only kill dates from in situ materials provide

Fig. 1 Injuries in *Larix decidua* Mill: (a) injured stem (b) cross section with overgrowth starting from the lateral edges of the injury. (c) Callus tissue as observed in the overgrowing cell layers bordering the injury. the precise location of the glacier when the tree was killed, detrital material having been killed some unknown distance up-glacier cannot yield such data.

Tree Reactions to Earth-Surface Processes

Apart from the site-specific information common to many trees at any site (e.g., genetic information, age, or climatic conditions), individual trees also record the effects of mechanical disturbance caused by external processes. Trees can be injured, suffer breakage of their crown or branches, and have their stems tilted, partially buried, or their roots exposed. Evidence of these events can be recorded in the tree-ring series of affected trees (Fig. 1). The analysis of geomorphic processes

Fig. 2 (a) Tree morphology and (b) cross sections of a tilted *Larix decidua* Mill. (c) Increment curves of a *Picea abies* (L.) Karst. tree tilted by a debris flow in 1922

through the study of growth anomalies in tree rings is called dendrogeomorphology (Alestalo 1971). Dendrogeomorphic research is normally based on the “process–event–response” concept as defined by Shroder (1978) where the “process” is represented by any geomorphic agent, e.g., debris flows, snow avalanches, or rockfall (Stoffel et al. 2010). Individual geomorphic “events” that affect the tree may result in a range of growth “responses.” These “events” and associated “responses” are illustrated in the following paragraphs.

Mechanical disturbance and **wounding** are very common features in trees affected by geomorphic processes. When impact locally destroys the vascular cambium, increment cell formation is disrupted and new cell formation ceases in the injured segment of the tree (Fig. 1a, b). To minimize rot and insect attacks after damage, the injured tree will compartmentalize the wound and start production of chaotic callus tissue (callus tissue = mass of unorganized parenchyma cells in plant tissues formed after wounding; Fig. 1c) at the edges of the injury (Shigo 1984). The extent of wound healing greatly depends on the annual increment rate, the age of the tree, and on the size of the scar. After injury, tangential rows of traumatic resin ducts (or TRD = compact and continuous rows of resin canals formed as a result of cambium damage. TRD are an excellent proxy to date mass movement-induced mechanical impact in trees; Fig. 1d) are produced in the developing secondary xylem of certain conifer species, e.g., *Larix* sp., *Picea* sp., *Pseudotsuga* sp., or *Abies* sp. (Stoffel 2008). They extend tangentially and axially from the injury (Bollschweiler et al. 2008; Schneuwly et al. 2009). When wounding occurs during the vegetation period of the tree, resin production will start a few days after the event and ducts emerge within 3 weeks after the disturbing event. Therefore, when analyzing cross sections, the intra-seasonal position of the first series of TRD can be used to reconstruct previous events with monthly precision (Stoffel et al. 2008; Stoffel and Hitz 2008). In broad-leaved species, cambial damage will initiate various anatomical responses, among those a reduction vessel sizes (Arbellay et al. 2010, 2012).

Inclination of the stem results from the sudden pressure induced by geomorphic processes directly, by the associated deposition of material (e.g., avalanche snow, debris-flow material), or

Fig. 3 (a) Sedimentation and subsequent die-off of trees after sedimentation. (b) Microsection showing an abrupt growth decrease in *Castanea sativa* Mill. (c) Several levels of adventitious roots in *Populus deltoides* Bartr. ex Marsh

by the slow but ongoing destabilization of a tree through landslide activity or erosion (Lundström et al. 2009). **Tilted trees** (Fig. 2a) are common in many areas affected by geomorphic processes and have therefore been used in many dendrogeomorphic studies to date previous events (Braam et al. 1987). Subsequent growth in the trunk of a tilted tree will attempt to restore its vertical position, and the reaction will be most clearly visible in that segment of the tree to which the center of gravity has been moved to through the inclination of the stem axis. In the tree-ring record, eccentric growth (and related reaction wood; Fig. 2b, c) will be visible after a tilting event and thus allow accurate dating of the disturbance. In coniferous trees, compression wood will be produced on the underside of the trunk. Individual rings will be considerably larger and slightly darker in appearance as compared to the upslope side. The difference in color results from much thicker and rounded cell walls of early- and latewood tracheids (Timell 1986). Multiple tilting events in the same stem may be recognized by changes in the amount, color, or orientation of reaction wood series in the ring series. In contrast, stem tilting in broad-leaved trees leads to the formation of tension wood on the upper side facing the tilting agent. Broad-leaved trees also react upon tilting with ultrastructural modifications that are only visible when studied on microsections (Pilate et al. 2004). In addition to the formation of different types of reaction wood, trees may also respond with reduced growth after tilting (Mayer et al. 2010).

Debris flows, floods, landslides, or “dirty” snow avalanches may **bury trees** by depositing material around their stem base (Fig. 3a). Growth in these trees will normally be reduced as the supply of water and nutrients will be temporarily disrupted or at least limited (Fig. 3b; Kogelnig et al. 2013). If stem burial exceeds a certain threshold, trees will die from a shortage in water and nutrient supply. According to case-study results from the Italian Dolomites (Strunk 1991), *Picea abies* (L.) Karst. may tolerate a maximum burial depth of 1.6–1.9 m in environments dominated by fine-grained debris flows composed of calcareous material. Occasionally, buried trees produce adventitious roots close to the new ground surface. As adventitious roots are typically formed in the first years after burial, the moment of root sprouting can be used to derive an approximate date for the sedimentation processes (Strunk 1991).

Bouncing rocks and boulders, debris in flowing water, debris flows and lahars, or the windblast of snow avalanches may cause **decapitation of trees** or the removal of branches. The loss of the crown or branches is more common in bigger trees, when stems have lost their flexibility. Apex

Fig. 4 (a) Exposed roots of *Pinus sylvestris* L. (b) In *Abies alba* Mill., larger increment rings with distinct latewood are formed after sudden exposure (dashed red line). (c) Following sudden exposure, the arrangement of vessels in *Fraxinus excelsior* L. changes from diffuse porous to ring porous. (d) In addition to cell changes, tension wood is formed in this root of *Acer pseudoplatanus* L.

(apex = uppermost part or growing tip of a plant) loss has also been observed as a result of rockfall impacts close to the ground level. In such cases, the sinusoidal propagation of shockwaves in the stem results in the break-off of the crown. This phenomenon has been described as whiplash or a “hula-hoop” effect (Lundström et al. 2009). Trees react upon decapitation or branch loss with distinct radial growth suppression. One or several lateral branches will form a “leader” that replaces the broken crown, resulting in the tree morphology called “candelabra” growth (Butler and Malanson 1985).

Erosional processes and the (partial) denudation of roots may generate different growth reactions, both in the stem and in the exposed roots (Fig. 4a). The type and intensity of the reaction(s) will depend on the nature of the erosive event, which may be instantaneous or progressive and gradual. If several roots are completely denuded during a sudden erosive event (e.g., debris flow, lahar, flood, or landslide), they are no longer able to fulfill their primary functions

and quickly die. The tree subsequently suffers from a shortage of water and nutrient supply, resulting in suppressed tree growth and the formation of narrow rings in the stem (LaMarche 1968). In cases where only part of a root is exposed and its outer end remains in the ground, the root will continue to grow and fulfill its functions. In the exposed root, however, anatomical changes will occur and individual growth rings similar to those in the stem or branches will be formed (Fig. 4b, d). The localization of this change in the tree-ring series may allow determination of the moment of exposure (Corona et al. 2011). The continuous slow exposure of roots is usually caused by gradual processes and relatively low denudation rates, e.g., by overland flow; the slow opening of cracks in soils (e.g., soil creep, landslides) and in disintegrated bedrock, along rivers, streams, lakes, and oceans (floods, shore erosion); as well as with faulting activity and displacements in relation to earthquake activity (Jacoby et al. 1988, 1992). Provided that the roots are gradually exposed with time, it is also possible to determine the erosion rates in such cases (Stoffel et al. 2013a).

Geomorphic processes can **eliminate trees** along channels or couloirs (couloir = French for “passage” or “corridor,” used to refer to a narrow gully with a steep gradient in a mountainous terrain) through uprooting and stem breakage and leave neighboring trees intact. This phenomenon can be observed with, e.g., rockfalls, debris flows, lahars, extreme floods, landslides, or snow avalanches. The uninjured survivor trees have less competition, more light, nutrients, and/or water. As a consequence, they may start to produce larger increment rings. However, observations indicate that this growth release in survivor trees can be delayed and therefore this reaction cannot always be used to date past destructive events with yearly precision. Nevertheless, the growth release in survivor trees can corroborate the dating of events that have been identified from evidence in other trees at the same site, e.g., from scars, tilted stems, etc. (Stoffel and Corona *in press*).

Many different earth-surface processes can eliminate surface vegetation including entire forest stands, leaving no direct dendrogeomorphic evidence. In such cases, **germination ages of trees growing on bare surfaces** can be used to estimate the time of creation of new landforms and the disturbance event. This approach provides a minimum age for that surface and has frequently been used to date landforms or assess the minimum time elapsed since the last devastating event in snow avalanche couloirs, debris-flow channels, or floodplains (Sigafos 1964; Pierson 2007). It involves estimating the time between the exposure of the surface and the germination of the first surviving seedling on that surface. This “ecesis” estimate varies with the environment, substrate, available seed sources, and several other factors. Problems of ecesis determination have been extensively discussed in studies that attempt to date the formation of glacier moraines (McCarthy and Luckman 1993) where ecesis estimates may vary from a few years to several decades.

Field Approach and Sampling Design

The types of damage to trees described in the preceding section may result from a wide variety of earth-surface processes. Linkage between the damage and the causative process depends on a critical evaluation of the sampling site. In many cases, investigations are undertaken with a specific context where the process or processes involved are known and appropriate sampling methods and sampling design may be applied. These vary considerably with the nature of the process or investigation and are best discussed in the specific context of individual processes, e.g., the sampling network needed to define past earthquake activity may be very different from that required to reconstruct the history of snow avalanches and debris flows on a large debris cone.

At an individual site the choice of sampling design and selection of the trees to be sampled will depend on the purpose of the investigation and the processes or hazards being sampled. The sampled area and number of trees sampled may be very small and specific (e.g., on a small landslide) or may involve systematic sampling of a larger area (e.g., within a large runout zone of a snow avalanche) or target individual trees damaged at the margins of an event. As a rule of thumb, processes that tend to spread considerably will likely leave larger spatial footprints and will thus be visible in a larger number of trees. In the case of landslides, a sample size of 50 trees seems sufficient, a slightly larger sample size (100 trees) appears appropriate for snow avalanches, and at least 150 trees are needed to characterize debris flows appropriately (Stoffel et al. 2013b). The sample size in rockfall studies will depend on the size of the study site, stand density, and mean rock sizes (Trappmann et al. [in press](#)). The choice of the individual trees sampled is based on an inspection of the stem and on the location of the trees with relation to the processes studied.

The tree-ring record of growth disturbances created by past events is analyzed with cross sections, wedges, or increment cores. Cross sections or wedges are normally taken at the location of the growth disturbance and provide an excellent and very complete insight into the tree's history. However, in many locations (e.g., protection forests, National Parks), felling may be prohibited or ill-advised for aesthetic or safety reasons. Most tree-ring studies thus use cores extracted with an increment borer. The nature of visible growth defects observed in the tree's morphology will influence sampling height, sampling directions, and minimum number of samples to be taken per tree.

In trees with visible **scars**, previous geomorphic events are most easily dated through the destructive sampling of trees and the preparation of cross sections taken at the location where the injury is largest. This approach will facilitate an accurate and intra-seasonal identification of the onset of **callus tissue** (and **TRD**) formation and therefore allows a reconstruction of the impacting event with very high temporal resolution. Alternatively, wedges can be sawn from the overgrowing callus and an increment core extracted from the side opposite to the wound (Arbellay et al. 2010).

Tilted stems are usually analyzed with at least two increment cores extracted per tree, one in the direction of the tilting and the other on the opposite side of the trunk. The reaction wood will be visible on the tilted side in conifer trees (= compression wood) and on the side opposite to the tilting direction in broad-leaved trees (= tension wood). Individual cores are best extracted at the location where tilting is strongest based on an outer inspection of the tree morphology. However, in situations where multiple tilting events may vary in direction, e.g., in snow avalanche tracks, additional cores, transverse to the downslope direction, may be needed to develop a more complete record.

In the case of **buried stem bases**, the sampling of two increment cores in opposite directions (ideally from the upslope and the downslope side) will normally allow accurate reconstruction of the event that has led to the sedimentation of material around the stem's base. It is best to sample these trees as close to ground level as possible (ca. 20–40 cm) to extract a maximum number of tree rings and obtain maximum information. However, the influence of roots should be avoided.

The analysis of **exposed roots** is normally based on cross sections, as they regularly show partially or completely missing rings. The position of samples needs to be carefully noted with respect to the ground surface or the non-eroded parts of the root. These samples are essential for the understanding and interpretation of continuous erosion processes and the determination of denudation rates (Stoffel et al. 2013a).

The **germination of trees** on new landforms is best determined by counting the annual growth rings in increment cores taken from the root crown level (root crown = also known as root collar or root neck; part of a root system from which a stem arises and where vascular changes between the

stem and the roots occur). However, branches, obstacles, and rot may sometimes require sampling positions higher up on the stem. In these cases, an age correction factor needs to be added to compensate for the time a tree takes to grow to sampling height. A simple height-age correction can be achieved by dividing the tree height by the number of tree rings to get an average rate for the yearly apical increment.

In some cases a reference tree-ring chronology may need to be developed from a nearby forest stand to assist in cross-dating of trees at the sampled site to verify the age assignment of rings. Adequate sample size varies between species and also depends on the strength of the common signal. In general, 20–30 trees is a useful guide for most species to minimize the potential influence of geomorphic processes and hidden growth disturbances.

Sample Analysis and Interpretation

Ring widths of the disturbed samples may also be measured and the series compared graphically or statistically with the reference chronology. These tools also allow for an assessment of cross-dating accuracy between ring-width series of individual disturbed trees and the reference chronology. Once all tree-ring series are checked, individual growth curves may be analyzed visually to identify the tree's reactions to geomorphic processes, e.g., the initiation of abrupt growth reduction or releases. In addition, the microscopic appearance of the cells may be investigated to yield further evidence of disturbance. Other features, e.g., callus tissue overgrowing scars or the presence of TRD formed following cambium damage, can only be identified through a visual inspection of the cores and cross sections. All growth reactions identified in the samples are noted in order to identify disturbance events. Except for processes with limited volumes (e.g., single rocks or boulders involved in rockfalls), one growth disturbance identified in a single tree is not considered sufficient evidence to identify an event, and therefore the identification of events needs to be based on quantitative or semiquantitative thresholds (Stoffel and Bollschweiler 2008; Stoffel and Corona [in press](#)).

Synopsis

The initial employment of tree rings in geomorphic studies was simply as a dating tool and rarely exploited other environmental information and records of damage contained within the tree. However, these unique, annually resolved, tree-ring records preserve valuable archives of past earth-surface processes on timescales of decades to centuries. As many of these processes are significant natural hazards, understanding their distribution, timing, and controls provides valuable information that can assist in the prediction, mitigation, and defense against these hazards and their effects on society. This entry provides many illustrations of these themes, demonstrating the application of tree rings to studies of snow avalanches, rockfalls, landslides, floods, earthquakes, wildfires, and several other processes. It illustrates the breadth and diverse applications of contemporary dendrogeomorphology and underlines the growing potential to expand dendrogeomorphic research, possibly leading to the establishment of a range of techniques and approaches that may become standard practice in the analysis and understanding of earth-surface processes and related natural hazards in the future.

Polymerase Chain Reaction DNA Amplification

Martyna Molak*

School of Biological Sciences, University of Sydney, Sydney, Australia

Definition

Polymerase chain reaction (PCR) is a method of amplifying DNA from biological samples. This makes it possible to determine the DNA sequence, using techniques such as Sanger sequencing.

Most genetic analyses involve the study of DNA sequences. To obtain these data, the target DNA needs to be amplified so that it can be distinguished from the rest of the DNA present in a biological sample. PCR is a technique that is routinely used to amplify DNA (Mullis et al. 1986; Mullis and Faloona 1987).

PCR requires the design of short DNA fragments (primers) with sequences that match the regions flanking the genetic marker being targeted (Fig. 1). These are added to a mixture of DNA (extracted from the biological sample), a DNA-replicating enzyme (polymerase), basic units for building new DNA molecules (dNTPs), and several other reagents. This mixture is subjected to a cycle of temperature changes. First, high temperature causes DNA to unwind and its two strands to separate (denaturation). Then hydrogen bonding causes the primers to attach specifically to matching sections of DNA (annealing). In the final part of the cycle, polymerase uses the original DNA strand as a template for copying the nucleotide sequence and attaches dNTPs to the new strand that has been started by the primers (elongation). This process is repeated a large number of times, with each cycle causing the number of target DNA molecules to double. Using PCR, the amount of target DNA can be massively increased, allowing the DNA sequence to be determined using other techniques.

Electron Spin Resonance Dating of Fossil Tooth Enamel

Mathieu Duval*

ESR dating laboratory, Geochronology program, Centro Nacional de Investigación sobre la Evolución Humana (CENIEH), Burgos, España

Synonyms

[Electron paramagnetic resonance \(EPR\) dating of fossil tooth enamel](#)

Definitions

Electron spin resonance (ESR) dating: a chronometric dating method based on the evaluation of the exposure of some materials to natural radioactivity, which is quantified in terms of absorbed radiation dose and corresponds to the energy deposited in the matter by ionizing radiations.

D_E : equivalent dose. The total absorbed radiation dose as measured in the laboratory.

ka: 1,000 years.

Ma: 1,000,000 years.

Introduction

The first ESR dating applications to fossil bones were published in the early 1980s (e.g., Ikeya and Miki [1980](#)). Given the potential of this kind of material, studies were quickly reoriented toward fossil tooth enamel, which has more suitable characteristics for dating (Grün and Schwarcz [1987](#)). Then, the method progressively gained in accuracy over the following decades, especially via a better understanding of the ESR signal of fossil enamel and its behavior with the absorbed dose. A major advance in ESR dating of enamel resulted from the introduction of a method combining ESR and U-series data in order to model the uranium (U) uptake into dental tissues, thus constraining the uncertainty of the resulting dose rate (Grün et al. [1988](#)). This definitely helped to convert the method into a valuable tool to date fossil remains beyond the ^{14}C time range.

Tooth Enamel: A Natural Dosimeter

From a mineralogical point of view, enamel is mainly made of carbonated hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) (90 %, vs. ~70 % for dentine and bone), water (~3 %), and organic matter (<1 %) (Elliott [2002](#)). Enamel is denser and more compact than dentine or bone, with larger hydroxyapatite crystals, making it less sensitive to diagenetic changes in terms of microstructure, chemical composition and dissolution/recrystallization processes (e.g., Dauphin and Williams [2004](#); Kohn et al. [1999](#)).

*Email: mathieu.duval@cenieh.es

Fig. 1 ESR spectrum of fossil tooth enamel. In addition to the main radiation-induced ESR signal generated by CO_2^- radicals, there are several minor contributions from other species (see Grün 2000b and references therein): (i) there is a septet centered on the main CO_2^- signal at $g = 2.0032$ (labeled “a”; only five lines are visible on that magnetic field range) formed by a free dimethyl radical; (ii) another isotropic line (marked “b”) at $g = 2.0115$ might be attributed to CO_3^- ; and (iii) the isotropic line at $g = 2.0056$ (marked “c”) is usually attributed to a free radical, probably SO_2^- . In ESR dating, ESR intensities are usually extracted by peak-to-peak measurements between T1 and B2.

The dosimetric properties of tooth enamel have been known for more than 40 years (e.g., Brady et al. 1968), and ESR is capable of measuring absorbed dose from only a few tens of mGy to several thousands of Gy (e.g., Fattibene and Callens 2010; Duval et al. 2009). Enamel is now internationally recognized as a valuable natural ESR dosimeter, especially used in the field of retrospective dosimetry for persons accidentally exposed to ionizing radiations (e.g., IAEA 2002 and references therein).

ESR Signal of Tooth Enamel

The ESR signal of tooth enamel is an asymmetric composite signal defined by three peaks at $g \sim 2.0032$ (T1), $g \sim 2.0006$ (B1), and $g \sim 1.9971$ (B2) (Fig. 1). Although many contributors to this signal have been identified (mainly carbonate-derived radicals and some oxygen radicals: Callens et al. 1998; Fattibene and Callens 2010), the major contribution is related to CO_2^- radicals.

Up to seven types of CO_2^- radicals have been identified as contributing to the main radiation-induced ESR signal (Brik et al. 2000), but the system is nevertheless usually simplified by considering three main types of CO_2^- (Fattibene and Callens 2010; Joannes-Boyau and Grün 2011): one isotropic at $g = 2.0006$ and two anisotropic CO_2^- radicals, an axial one ($g_{\perp} \sim 2.003$; $g_{\parallel} \sim 1.997$) and an orthorhombic one ($g_x \sim 2.003$; $g_y \sim 1.997$ and $g_z \sim 2.001$). These CO_2^- radicals are usually divided in two categories: the non-oriented radicals, which exhibit a powder spectrum, and the oriented CO_2^- radicals, whose ESR signal may significantly change according to the angular position of the enamel fragment in the ESR cavity. Both groups have different characteristics in terms of thermal stability or microwave saturation. Furthermore, their relative proportions in the ESR signal may not be the same in the natural and irradiated spectrum. Irradiation or heating processes might induce some transformation from one category to another,

Fig. 2 Tooth geometry for dose rate calculations (Modified from Rink 1997). Shown here is the sediment-cementum-enamel-dentine geometry. (*) is the removed enamel thicknesses (a few tens of μm) from both sides of the enamel layer. *Top right*: examples of occlusal views of horse fossil teeth (**a**, **b**, and **c**) from various Spanish archaeological sites (scale = 1 cm)

which would generate some uncertainties in the evaluation of D_E (Joannes-Boyau and Grün 2011; Brik et al. 2000).

Age and Dose Rate Equations

The basic ESR age equation for tooth dating may be expressed as follows:

where D_E is the equivalent dose, i.e., the total dose (Gy) absorbed by the enamel during the time elapsed between the death of the animal ($t = 0$) and the sampling ($t = T$), and $D(t)$ is the mean dose rate (in Gy/ka or $\mu\text{Gy/a}$).

Basically, the total dose accumulated in the enamel over time is the result of a combination of various contributions coming from radioactivity in the tooth itself and the surrounding environment. The specificity of tooth dating relies on the complex system that has to be considered. Indeed, a tooth is usually made by several tissues of varied thickness and composition. Therefore, accurate age calculation must rely on careful consideration of the geometry of the enamel layer and its surrounding environment (Fig. 2).

Except for the cosmic dose, each component of the dose rate is directly derived from the contributions of the α -particles, β -particles and γ -rays emitted by the radioactive elements located within the sample and its surrounding environment (mainly U and Th decay products as well as ^{40}K). Because each kind of ionizing radiation has a specific penetration range in matter ($\sim 20\text{--}40\ \mu\text{m}$ for α -particles, $\sim 2\ \text{mm}$ for β -particles, and $\sim 30\ \text{cm}$ for γ -rays), some of their respective contribution has to be attenuated or even removed depending on the size of the sample dated.

For dental tissues, only the U decay products contribute significantly to the enamel dose, because tissues are usually assumed to be free of Th decay products as well as ^{40}K (e.g., Grün and

McDermott 1994). Given the typical thickness of the enamel (a few mm), it is usually assumed that self-absorption of internal γ -rays is negligible. Thus, the internal dose rate from the enamel is only made by α - and β -components, which are corrected by an alpha efficiency factor and a self-absorption factor, respectively. For the other tissues, we need to consider only an attenuated beta component, since the external α -particle contribution is removed by abrading both sides of the enamel layer over a few tens of μm . The magnitude of the beta component depends on the initial and removed thicknesses of the enamel layer as well as water content in the tissues. Finally, the sediment typically provides only a γ -ray contribution to dose rate (unless the enamel is in direct contact with sediment), corrected by water attenuation, and derived from the measured elemental concentrations of U, Th, and K. Consequently, in case of a geometry sediment-cementum-enamel-dentine (Fig. 2), the dose rate equation may be expressed as follows:

where $C_{\text{U, Th, K}}$ is the concentration in U, Th, and K measured in each dental tissue and sediment; $W_{\alpha, \beta, \gamma}$ is the water attenuation for α -particles, β -particles, and γ -rays; $F_{\text{U, Th, K; } \alpha, \beta, \gamma}$ is the dose rate conversion factor depending on the kind of ionizing radiation and the emitter; k is the alpha efficiency; $S_{\text{U}\beta}$ is the internal beta self-absorption; and $A_{\beta 1,2}$ is the external beta attenuation for U-series elements. Equation (2) is valid when equilibrium is assumed within the U-series or Th-series decay products in the dental tissues and sediment. However, if disequilibrium is observed, more elements in each decay series have to be considered in the equation. Specific issues with disequilibrium in dental tissues and sediment may be found in Grün (1989) and Olley et al. (1996), respectively.

In case of enamel in direct contact with the sediment, Eq. (2) has to be modified by considering an external beta contribution from the sediment, instead of a tissue.

U-Uptake Modeling

Dental tissues behave as open systems for U-series elements. It is therefore crucial not only to measure the U-content but also to know its past evolution. To address this point, several parametric U-uptake models were proposed. The early uptake (EU) model assumes that U is incorporated shortly after burial (Bischoff and Rosenbauer 1981), i.e., an approximation of a closed system. The linear U-uptake (LU) model describes uptake with a constant rate since the time of burial (Ikeya 1982). The recent uptake (RU) model considers that all measured U-concentration in the sample was taken up in very recent times (Blackwell et al. 1992). These parametric models allow some easy age calculations, but are based on unrealistic assumptions (i.e., the closed system assumption for the EU uptake). Additionally, the models oversimplify the complexity of U-uptake into the different tissues in some teeth (e.g., Grün 2009a). These models cause large uncertainties when uranium concentrations in the dental tissues are high, and the calculated age value may be then very sensitive to the U-uptake assumption (e.g., Grün and McDermott 1994; Duval et al. 2012).

To address the problem of the unknown U-uptake, Grün et al. (1988) suggested to combine ESR and U-series analyses and introduced a parameter p to describe the kinetics of the U-uptake in the dental tissue (US model). In comparison with the conventional models, the combined US-ESR method has the advantage that U-uptake history is not a priori assumed, but mathematically assessed according to the ESR and present-day U-series (U-concentration, $^{230}\text{Th}/^{234}\text{U}$ and $^{234}\text{U}/^{238}\text{U}$) data measured in each tissue. As a consequence, only one combined US-ESR age fits the available dataset (Grün et al. 1988). Moreover, the US-ESR approach considers the possibility of different uptake histories among the various dental tissues of a unique tooth, by calculating

Fig. 3 Example of ESR dose–response curve. A double saturating exponential (*DSE*) function is fitted through the experimental points, and D_E is obtained by extrapolation of the function to $Y = 0$

a specific p -parameter for each tissue. This approach also helps to overcome some limitations of the U-series dating method in some specific situations, beyond the time range of the U-series dating method (Grün et al. 2010) or in case of very recent U-uptake (e.g., Falguères et al. 2006).

However, the combined US-ESR approach has also several limitations. First, U-leaching from dental tissue cannot be modeled (Grün et al. 1988). By definition, the U-uptake history is mainly modeled from the U-series data measured in dental tissues. Consequently, the reliability of the calculated age is highly dependent on the accuracy of these U-series data. However, the latter may be influenced by many factors, such as the spatial homogeneity and preservation of the sample, or recent U-mobilization that may overprint past U-uptake history (Duval et al. 2011). Other models based on the combination of U-series and ESR data have been also developed, in particular to specifically address the issue raised by the occurrence of U-leaching in dental tissue (e.g., Shao et al. 2012) or the spatial variation of the U-series data (Pike et al. 2001), but their potential and limitations are not clearly defined yet. Finally, another variation of the US model was also proposed by Grün (2000a), the closed system (CS)-US model. This is based on a very specific assumption, i.e., the measured uranium content was incorporated into the tissues at the time corresponding to the apparent U-series age, providing thus a maximum possible age for the sample.

Standard Analytical Procedure: A Brief Overview

An ESR age estimate is the result of a long and complex analytical process, made by several steps associating fieldwork and laboratory procedures, which may be resumed as follows:

Sampling. Fossil teeth are collected directly from the site or chosen from collections. In situ measurements of the natural radioactivity should be performed at the exact place, or at least the closest possible, where the sample was collected.

Sample preparation. In the laboratory, the tooth is prepared by separating mechanically each dental tissue. The enamel is then cleaned on both sides to remove external α -particles contribution

and powdered, in order to avoid angular dependence of the ESR signal within the ESR resonator and to improve sample homogeneity.

D_E reconstruction by ESR spectrometry. The enamel powder is usually divided in one or several subsample aliquots that are irradiated at various increasing dose steps (additive dose method). Each aliquot is then measured at room temperature by X-band ESR spectrometry in order to study the behavior of the ESR signal with the increasing dose values. The ESR intensity is extracted from each spectrum, usually by peak-to-peak measurements between T1 and B2 (Fig. 1). A mathematical function, usually a single saturating exponential or a double saturating exponential function (Duval et al. 2009), is fitted through the experimental data points and its extrapolation to the abscissa axis ($Y = 0$) provides the D_E value, corresponding the total dose absorbed by the tooth enamel since the death of the animal (Fig. 3).

Evaluation of dose rate. If the gamma dose rate has to be assessed in situ, the external beta dose rate contribution coming from the sediment should be assessed in the laboratory, from the sediment sample that was collected around the tooth. Usually, the dose rate is derived from the activities or concentrations of the radioactive elements present in the sample and its surroundings. These concentration data are converted into dose values using known factors (Guérin et al. 2011) and corrected according to several parameters, such as the water content (e.g., Grün 1994), the geometry of the sample, its thickness and density for β -attenuations (Brennan et al. 2000), and the alpha efficiency (Grün and Katzenberger-Apel 1994). In case of the combined US-ESR approach, U-series data from each dental tissue (U-concentration, $^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{234}\text{U}$) is required in order to model the uranium uptake. Finally, the cosmic dose rate contribution is usually assessed via tables and is corrected according to various factors like the ground density, depth of the sample, altitude, and latitude (Prescott and Hutton 1994).

ESR age estimate. Basically, two main non-commercial programs are most widely used for age calculation on teeth: these are the ROSY software which enables age calculation based on the parametric U-uptake models (Brennan et al. 1999) and the DATA program, providing combined US-ESR age estimates (Grün 2009b). ESR ages are usually quoted $\pm$ one standard deviation. Relative age uncertainties are rarely $<10\%$ (Rink 1997) and are more likely between 10 % and 20 %.

Time Range Applicability

It is usually considered that the optimum time range application for ESR dating of tooth enamel lies between ~ 50 and ~ 600 ka. Nevertheless, under some specific conditions, the time range limits may be potentially pushed from <1 ka to $\sim 2\text{--}3$ Ma.

For modern ESR samples, the lower dating range is in general mainly driven by (i) the radiation sensitivity of the material and (ii) the sensitivity of the tools employed for dose reconstruction, including the ESR spectrometer. Recent developments in ESR dosimetry of enamel lead to define a detection limit of several tens of mGy (Fattibene and Callens 2010). The detection of background dose values with ESR spectrometry (e.g., Toyoda et al. 2011) suggests the possibility of dating almost present-day (i.e., last millennium) materials, as soon as radionuclide concentrations in the sample and its surrounding environment can be accurately assessed. However, a rapid overview of the published works indicates that ESR dating is rarely applied to fossil teeth younger than ~ 20 ka.

The upper limit of the datable age range is mainly constrained by two parameters: (i) the saturation of the ESR signal with the absorbed dose and (ii) the thermal stability of the paramagnetic centers. Depending on the number of traps available in the crystal lattice, the nature of the

analyzed paramagnetic center and the intensity of the dose rate, the intensity of the ESR signal may saturate rapidly or more slowly when the material is absorbing ionizing radiations. In the case of teeth, the saturation level in enamel is very high and absorbed dose values up to several thousands of Gy have been detected (e.g., Duval et al. 2009). The second parameter is the thermal stability of the paramagnetic centers, which describes the mean life of a trapped electron at the defect site. Schwarcz (1985) assessed the lifetime of the ESR signal of tooth enamel to ~1 Ga at 25 °C, suggesting then a possible application over a few Ma. As a rule of thumb, the ESR signal must have a mean life of at least one order of magnitude higher than the age of the sample dated (Grün 2007) in order to avoid systematic uncertainties due to decay of the signal during burial. However, when dealing with old samples (>800 ka), the main complication lies in the U-uptake modeling for the dose rate reconstruction. Indeed, U-leaching may be frequently observed for such time range, making the application of the combined US-ESR approach extremely difficult (e.g., Duval et al. 2012). Only two situations are possible in which ESR dating could potentially be accurate to ages up to ~2–3 Ma: (i) no apparent U-leaching is detected in dental tissues, which may sometimes occur for Early Pleistocene sites (e.g., Duval et al. 2012), or (ii) the tooth samples show very low U-concentration in dental tissues (e.g., Schwarcz et al. 1994), decreasing the relative contribution of dental tissues in the total dose rate calculation in comparison with sediment.

Main Strengths and Weaknesses of the ESR Dating Method Applied to Fossil Teeth

ESR dosimetry of tooth enamel is now an international reference method (Fattibene and Callens 2010), demonstrating the great potential of this material for dose reconstruction. In addition, ESR is one of the very few dating methods that may be applied to fossil remains and can provide a direct measurement of age of hominid or animal occupation in any sedimentary context. ESR dating is also one of the very few alternatives for dating fossils, including hominid remains, beyond the ¹⁴C and U-series dating time range (Grün et al. 2010).

In contrast, the complexity and the length of the analytical process are likely the main limitations of this dating method. Many parameters (>15) have to be considered and assessed for the age calculation, with a direct consequence on the age precision (final age errors are usually > 10 %). In addition, at least several months are usually required to fully process a sample, and the analytical procedure involves an array of equipment that must be carefully and accurately calibrated (e.g., U-series analyses facilities, ESR spectrometer, gamma irradiation source, high-resolution gamma spectrometer, portable gamma spectrometer). Finally, another limitation lies in the sampling itself. In the case of historic excavations, it may be difficult to precisely locate (geographically and stratigraphically) the sample's provenance, which induce many uncertainties on the external dose rate associated to sediment and thus on the final age estimate.

Some Examples of Recent Developments in the Field

ESR Measurement of Enamel Fragments

Working with enamel fragments significantly reduces the destructive aspect of the method. However, this technique implies a complex analytical procedure (e.g., Joannes-Boyau and Grün 2011). Nevertheless, ESR analyses of enamel fragments, unlike powder, may provide useful information about the composition of the ESR signal: each component contributing to the

radiation-induced ESR signal may be potentially isolated and studied separately, which may be of special interest for reducing potential source of error in the D_E assessment (Joannes-Boyau and Grün 2011).

High-Resolution Mapping of Radioelement Distribution in Dental Tissues

The combination of a laser ablation system with an ICP-MS (LA-ICP-MS) recently opened huge perspectives for the U-series analyses of dental tissues (e.g., Eggins et al. 2003), yielding high-resolution U-series data in a short acquisition time and with minor sample preparation. For example, maps of spatial distribution of U-series elements in dental tissues may be obtained (e.g., Duval et al. 2011). This is of special interest for studying U-mobility into dental tissues and may be particularly useful to identify domains in the teeth that are suitable for ESR dating.

Direct Dating of Hominid Remains

The recent development of ESR measurements on enamel fragments combined with LA-ICP-MS U-series analysis now permits analysis of human teeth without causing any visible damage (e.g., Grün et al 2006). Such an approach offers new perspectives for the ESR method, by giving access to direct dating of inestimable hominid remains that are beyond the ^{14}C time range.

ESR Dating of Early Pleistocene Fossil Teeth

“Old” samples result in many challenges that are not encountered in younger samples and which make the application of the combined US-ESR approach especially complex (see Duval et al. 2012 for further details). Nevertheless, recent methodological developments showed that ESR may be a useful tool to constrain the chronology of the earliest hominid occupations in Eurasia and Africa during Early Pleistocene times (e.g., Duval et al. 2012).

Summary

ESR dating is one of the very few dating methods that may be applied to fossil remains, resulting in a direct measurement of the age of hominid or animal occupations in any sedimentary context. The challenge in applying ESR dating to fossil teeth lies in the requirement to model U-uptake kinetics into dental tissues, which are known to behave as open systems for U-series elements. So far, the combined (or coupled) U-series/ESR dating approach provides the most reliable ESR age estimates. Under some specific conditions, this application may potentially cover the whole Quaternary time range.

Luminescence, Desert Dunes

Matt Telfer*

School of Geography, Earth and Environmental Science, University of Plymouth, Plymouth, Devon, UK

Synonyms

Dune chronostratigraphy; OSL dating

Definition

Luminescence dating. Geochronological method relying on the dosimetric properties of common minerals to accumulate a trapped charge proportional to burial age and the dose rate.

Desert dunes. Discrete aeolian landforms, typically dominated by sand, found in dryland regions of the world.

Introduction

In many respects, desert dunes are the ideal medium for the application of luminescence dating. They are typically dominated by sand-sized quartz, occur in an environmental setting typified by intense sunlight and relatively rapid aeolian sedimentation (leading to well-defined “bleaching” events), and are usually characterized by a lack of other dateable material. Crucially, their dynamism overlaps very closely with the typical range of timescales to which luminescence dating is applicable (i.e., $10 - 5 \times 10^5$ years). It is, thus, unsurprising that it was desert dunes that saw the first geoscience application of luminescence dating, with Singhvi et al.’s (1982) landmark geochronological study of the Indian Thar desert. The earliest studies used heat as the stimulation source (thermoluminescence, or TL), and indeed TL continued to be applied to dune sequences routinely for the next 20 years or so, but Huntley et al.’s (1985) use of light (Optically Stimulated Luminescence, or OSL) has become by far the most commonly used method today. It was not, however, merely the ability to date dunes directly for the first time that drove a rapid expansion in interest in luminescence dating of desert dunes; the research agenda was driven primarily because it had long been recognized that desert dunes are among the most dynamic and environmentally sensitive of earth’s terrestrial systems.

The Growth of Luminescence Dating of Desert Dunes

Despite Pye and Tsoar’s (1990) cautious assertion that “many difficulties remain to be resolved before luminescence dating of sand can be regarded as entirely reliable,” a key feature of today’s research was established early on; it was not generally the active dunes of the world’s hyperarid regions that attracted the most attention. It was the fully or partially stabilized dunes of the desert

*Email: matt.telfer@plymouth.ac.uk

Fig. 1 Many studies have found desert dunes present an ideal medium for luminescence dating, with samples demonstrating: (a) bright, fast-component-dominated quartz OSL signals; (b) well-defined growth curves with low recuperation and good recycling characteristics; (c) and (d) good repeatability of equivalent dose measurements between aliquots, shown here as both as ranked and radial plots

margins. The dunes of Australia (e.g., Gardner et al. 1987), Southern Africa (e.g., Buch et al. 1992), and the Western USA (e.g., Stokes and Gaylord 1993) attracted particular attention. These studies investigated a wide range of dune morphologies. Many studies focused on individual sites or localized areas, but some, notably Nanson et al. (1992) and Stokes et al. (1997), were more ambitious in scope, aiming to provide regional-scale syntheses of late Quaternary aridity. In general, desert dunes proved highly favorable for the method, typically offering well-defined growth of the OSL signal and excellent repeatability (best defined by overdispersion sensu (Galbraith et al. 1999)). Figure 1 demonstrates a typical shine-down curve, growth curve, and dose distribution for a favorable desert dune sample. Thus, the majority of studies have focused less on the technical suitability of dune sands for luminescence dating and more on the interpretation of the results of the dating work.

Some studies (e.g., Lomax et al. 2007), however, have encountered poor repeatability of individual aliquots (i.e., high overdispersion) from dune sands. Such effects are usually attributed to heterogeneous dose environments, inadequate bleaching at time of deposition, or postdepositional mixing of sediment. The latter is often considered the most significant problem in massively bedded desert dunes and has been investigated in detail (Bateman et al. 2007). The low moisture levels and typically homogeneous sediment are also usually assumed to lead to straightforward estimation of the dose rates, but as in other environmental settings dated with luminescence, dosimetric issues have perhaps sometimes been overlooked. In dunes which have periodically accumulated over long periods of time, the cosmic contribution to dose rate may be better estimated by an iterative procedure to model the varying overburden (Munyikwa 2000). Commonly assumed moisture contents for dunes may also have frequently been overestimated (Telfer and Hesse 2013).

Desert dune sands have also been used in methodological development of luminescence dating, although perhaps less frequently than might be expected, perhaps due to the difficulty of corroborating ages derived from new techniques with alternative dating methods. Nonetheless, Li and Li (2011) have applied post-IR IRSL (Infra-Red Stimulated Luminescence) to Chinese dune sands, with a view to extending the applicable age range of the method, and Fujioka et al. (2009) paired OSL and cosmogenic dating techniques to date the inception of an Australian dune field. Field methodologies have perhaps developed more rapidly in the study of desert dunes, with geophysical survey and augering methods used to achieve full-depth survey and sampling of dunes up to around 20 m depth. In a very few instances (e.g., Preusser et al. 2002), heavy duty coring equipment has been used to extract dateable sand cores in excess of 150 m length, but challenges remain with the recovery rate of such loose sediment.

Applications of Luminescence Dating of Desert Dunes

Although the methodological challenges of luminescence dating of desert dunes are less than some other environments (e.g., fluvial or glacial), the interpretation of ages obtained from dunes remains highly complex. The majority of studies of desert dunes around the turn of the millennium remained focused on paleoenvironmental studies, often with a view to paleoclimatic interpretation of the data; a significant minority of research, however, used the ability to provide chronometric control for dune development to improve understanding of geomorphology. It must be borne in mind that most dune systems will have involved repeated cycles of deposition and erosion, and an OSL age refers only to the most recent of these burial events, with important possible implications for the contextual interpretation of the age.

A wide range of dune types has been studied, with different dune types attracting different types of study on account of their differing geomorphological characteristics. For instance, the transition from active barchan dunes to stabilized parabolic dunes on the Canadian prairies over a period of ~200 years has been described by Wolfe and Hugenholtz (2009). Linear dunes are typically considered much more long-lived landforms, as their mode of formation does not lead to such frequent complete reworking of the dune body, and hence these are often seen as offering the greatest potential for long-term records of past aeolian environments. Star dunes, which include the largest dunes on earth, have proven challenging for dating studies, with full-depth sampling of large star dunes not currently achieved, but they have occasionally formed part of investigations into complex dune patterns (Beveridge et al. 2006).

Paleoenvironmental Applications

The prevailing paradigm of the 1990s was broadly that increased frequency of observed ages within a currently stabilized dune equated to past periods of aridity, although there were already conceptual models which suggested that dryland landscape response to external forcing stimuli may be more complex than this (Kocurek 1998). Some long-standing hypotheses were challenged, such as the assumption that the widespread arc of currently stabilized dunes in Southern Africa resulted from drier conditions during the Last Glacial Maximum (LGM) (O'Connor and Thomas 1999). Dunes offer a rare opportunity to establish paleowind directions, which has been exploited at both continental (e.g., Nanson et al. 1995) and regional scale (e.g., Holmes et al. 2008). Luminescence dating also allowed the direct dating of sites of high archaeological significance, such as the human remains from the lunette dune at Lake Mungo, Australia.

Fig. 2 Conceptual model of the drivers of net dune accumulation under changing climatic regimes, demonstrating the complexity of the linkage between external drivers and landform response. The presence of bedform/boundary layer interaction as a result of changes in aeolian accumulation is perhaps the most significant aspect introducing non-linearities into the system. This schematic is not intended to be exhaustive, and numerous other linkages and feedback could be proposed

More recently, however, a number of studies have begun to challenge the assumption that frequency of observed luminescence-derived dune ages is a direct proxy for past aridity. There are a number of reasons for this, and perhaps the most important is the spatial and temporal variability evident in the preservation of dune sands. As most dunes rework themselves during periods of reactivation, the sedimentary record from dunes is typically discontinuous. Some studies showed that adjacent dunes did not respond identically to what must have been identical climatic forcing (Telfer and Thomas 2007). Stone and Thomas (2008) sampled a dune at 0.5 m vertical intervals – a better resolution than had previously been attempted – and noted that if these data were subsampled to 1 m resolution (i.e., jack-knifing), there was worrying disparity between the conclusions drawn from some of the older ages. Such studies implied that the stochastics of net preservation in dune systems were complex and led Telfer et al. (2010) to investigate such interpretations via modeling, which suggested that current sample sizes were in most cases inadequate to interpret anything other than gross trends in the net accumulation rate in dunes.

Concurrent with increased realization of the implications of spatial variability in the preservation of dune records came increased questioning as to what the record of OSL-derived chronostratigraphies actually meant from a paleoenvironmental, or even paleoclimatic, perspective. Traditionally, an increase in observed frequency of dated samples was interpreted as increased aridity (e.g., Stokes et al. 1997). More recent work has identified a very wide range of possible drivers of net dune accumulation rates, and the complexity of the factors affecting dune accumulation is shown in Fig. 2 and must be considered site specific. The interpretations of Roskin et al. (2011) are a good example of current best practice, drawing in a wide range of additional data before drawing inferences on the driving factors in the region under investigation.

Geomorphological Applications

There have been fewer chronological studies of dunes with geomorphology as the primary aim, but those that have addressed processes and rates of landform formation have often been very successful. Luminescence-constrained chronologies offer a longer-term perspective than observational studies can allow, and although some dunes do currently move on timescales that can be usefully monitored in the field, or using remotely sensed data, it is also clear that many dunes have formed on timescales greater than 10^3 years.

In some instances, luminescence dates have been used to constrain the sequence of events in complex aeolian environments, thus helping in the understanding of complex interactions and feedbacks operating between the bedform and the moving atmospheric boundary layer (Lancaster et al. 2002). Luminescence dating has also been used at the landform scale to help elucidate long-term landform development, particularly in combination with ground-penetrating radar (GPR) to reveal internal stratigraphy of dunes (Bristow et al. 2005; Bristow et al. 2007). Telfer (2011) demonstrated that with sufficient sampling resolution, chronostratigraphies alone could inform long-term landform evolution studies, by demonstrating the complex extension of a Kalahari linear dune. Attempts have also been made to use the luminescence characteristics of dune sands to determine whether the dunes were formed in subaerial or subaqueous environments (Burrough et al. 2012).

Summary and Conclusions

Desert dunes are typically some of the least challenging environments in terms of getting successful luminescence dates. The challenge comes with the interpretation of these dates. It is not possible to take a limited number of samples in a nonsystematic manner from a stabilized dune field and extract a regional climatic signal of aridity. There is an urgent need for improved understanding of the long-term process geomorphology of dunes, and currently, the best way of using dunes as a geomorphological proxy of past environments is to consider them alongside other paleoenvironmental archives and to recognize the complexity of the climate change-landscape response relationship in dunes. That said, luminescence dating of dunes still offers an essential tool for understanding the nature and rates of aeolian processes at scales beyond those which can be observed directly. This will prove vital in the future for improved understanding of dryland landscape response to changing external stimuli, a pressing issue in the light of twenty-first-century climatic change.

Synonyms

[AAR, Protein diagenesis geochronology](#)

Definition

A method for estimating the relative age since death by assessing the extent of postmortem conversion of biological chiral forms of amino acids (L-enantiomers) to their nonbiological counterparts (D-enantiomers).

Introduction

Amino acid racemization (AAR) dating is a geochronological technique with a very long history. Over the past 60 years, many researchers and laboratories around the world have been involved with the development of the method and its application to diverse environments. Its time depth and applicability to a wide range of substrates are the main strengths of this method. Its main weakness is the fact that it is a molecular- rather than an atomic-scale reaction (cf. radionuclide decay), and as a consequence the rate is sensitive to temperature. Useful review articles for understanding the principles of AAR dating are those of Miller and Brigham-Grette (1989), Mitterer (1993), Rutter and Blackwell (1995), Johnson and Miller (1997), and Wehmiller and Miller (2000). In addition, two classic volumes on amino acid racemization were produced: *Biogeochemistry of Amino Acids* (1980), edited by Hare, Hoering, and King, and *Perspectives in Amino Acid and Protein Geochemistry* (2000), edited by Goodfriend and colleagues. Following a session on AAR dating that took place at the INQUA 2011 conference (Bern, Switzerland), a special issue of the journal *Quaternary Geochronology* (vol. 16, pages 1–198, April 2013, edited by Penkman and Kaufman) was published in 2013. This summarizes the current state of the art in AAR research. We refer the interested reader to these publications for gaining a more in-depth understanding of the vast field of protein diagenesis and its applications to geochronology.

Here we provide a basic toolkit for understanding the principles of AAR, beginning with the chemical mechanisms of protein diagenesis, summarizing briefly the history of the development of the technique, and then focusing in more detail on one of the methodologies of AAR dating that has been developed in more recent years: the intracrystalline protein diagenesis (IcPD) approach. While the method does not supersede more traditional approaches, it is an important step towards the integration of AAR and biomineralization studies. The two are deeply intertwined, as biomineral growth is controlled by proteins which are then trapped in the mineral framework and undergo postmortem degradation. Therefore, understanding the complexities of protein diagenesis should be

*Email: beatrice.demarchi@york.ac.uk

viewed in conjunction with an understanding of biomineral formation which, after death, will represent the protein's burial environment.

What Is an Amino Acid?

Amino acids, the building blocks of proteins, share a common chemical character, each containing a hydrogen atom (H), an amino group (NH_2), a carboxyl group (COOH), and an (R) group, or side-chain, bound to a central carbon atom (C). Amino acids have both amine and carboxylic acid functional groups and therefore can act both as an acid and as a base. Most proteins are built from sequences of 20 different amino acids; their chemical characteristics are determined by the –R group and their sequence in the protein by the genetic code (Fig. 1).

Fig. 1 A short peptide (Val-Ser-Phe-Leu-Gln) to illustrate side chains (–R groups) and the backbone structure formed by the condensation between the amino and carboxyl group of two amino acids (peptide bond). Proteins are typically composed of 50–1,000s amino acid residues

What Is Amino Acid Racemization?

Chirality

Consider your hands; left and right (in Latin, left is *laevo*, and right is *dextro*). Your hands have chiral symmetry: they are mirror images of each other and cannot be superimposed. As with your hands, so with all but the simplest molecules: the configuration of their atoms in space means that they too can exist in more than one form, which may be mirror images but cannot be superimposed. All of the amino acids that occur in proteins, except for glycine, which is the simplest amino acid, have at least one asymmetric carbon atom. They can therefore exist in two nonsuperimposable stereoisomers (enantiomers), termed (from the Latin) L- and D-forms. Some amino acids have two asymmetric carbon atoms and can exist in four different forms, known as diastereomers. Two of these amino acids, isoleucine and threonine, are commonly found in most proteins. L-isoleucine racemizes (or more accurately in the case of two asymmetric carbon atoms, epimerizes) almost exclusively to one form, called D-alloisoleucine. Because diastereomers have different chemical and physical properties, they are the easiest to measure and were therefore the first to be used for geochronology.

Dating

The basis of amino acid racemization (AAR) as a dating technique is the measurement of the relative proportions of the L- and D-chiral forms. In almost all living proteins, amino acids are present in the L-form. The most commonly encountered exceptions are bacterial cell wall biopolymers, collectively termed peptidoglycan. The presence of D-amino acids in peptidoglycan is a potential confounding factor, although it is useful to estimate microbial reworking.

Upon death L-amino acids will slowly and spontaneously convert to D-amino acids, which themselves spontaneously revert back to the L-form. Eventually, a situation of dynamic equilibrium is reached, where there is a 1:1 (so-called racemic) mixture of L- and D-amino acids. A simple mnemonic is that L-forms are found in “living” organisms and D-forms accumulate in “dead” ones. This interconversion reaction is called **racemization**.

Racemization analysis has been conducted on wood (Engel et al. 1977), on textiles (Moini et al. 2011), and in the biosciences on a range of tissues (skin, arteries, cornea) (Ritz-Timme and Collins 2002), but for geochronology **biominerals** are the preferred target. Amino acids have been reported in pyrite and have been isolated from soils and rocks, siliceous sediments, and bioapatites (enamel) (e.g., Kimber et al. 1994; Nardi et al. 1994; Hearty and Kaufman 2000; Murray-Wallace et al. 2001; Harada et al. 2002; Griffin et al. 2009), but most studies focus on **carbonate** biominerals, principally aragonite and calcite: mollusk shells, eggshell, ostracods, foraminifera, brachiopods, and corals (a selection of studies on carbonate biominerals: Bada et al. 1970; Wehmiller and Hare 1971; Wehmiller 1976, 1977, 1980, 1982; Masters and Bada 1978; Andrews et al. 1979; Davies 1983; Hearty et al. 1986; Miller et al. 1983; Müller 1984; Brooks et al. 1990; Goodfriend 1992; Bates 1993; Sejrup and Haugen 1994; Wehmiller et al. 1995; Goodfriend et al. 1996, 1997; Torres et al. 2000; Kaufman 2003; Barbour Wood et al. 2006; Kaufman et al. 2008, 2013; Hendy et al. 2012; Ortiz et al. 2013; Penkman et al. 2007, 2013).

Racemization proceeds at different rates according to (a) the chemical characteristics of the amino acid itself, (b) the position of the amino acid within the protein, and (c) burial temperature and other factors (pH, water availability, presence of cations and anions, microbial degradation). As we will see, factors operating in the burial environment can be *better* controlled if a closed-system fraction of amino acids (“intracrystalline”) is used for dating purposes. If all of these variables are known (or comparable between a set of samples), then the ratio between the D- and L-forms of a specific amino acid (also called D/L value) will reflect the age since death of the organism. This ratio will increase over time from a value of 0 (when the organism is alive, and no D-amino acids are present) to

1 (racemic equilibrium, where a 50–50 % mixture of L- and D-forms is present). Therefore, for a series of samples of increasing age, the D/L value will also increase: this is the basis for building relative chronological frameworks with AAR. These frameworks can then be calibrated, if the D/L value is measured on samples of known age – for example, a series of shells that have been dated by radiocarbon (Kosnik et al. 2008). This allows building calibrated chronological frameworks, which can then be used to date samples independently. However, many studies focus on Quaternary deposits, which lie well beyond the radiocarbon range: in this case, calibration must rely on other independent chronologies, for example, U-series, OSL, strontium isotopic stratigraphy, paleomagnetism, biostratigraphy, and sedimentary evidence (e.g., Wehmiller and Belknap 1982; Hearty et al. 1986; Penkman et al. 2011; Wehmiller et al. 2012). Calibration is especially important because pre-Holocene samples have experienced a number of glacial-interglacial cycles and have therefore been exposed to different burial temperatures, which prevent Holocene-based calibrations to be extended back to the Pleistocene (see also “► [Amino Acid Racemization, Paleoclimate](#)”).

A Brief History of the Technique

The first report of the presence of amino acids preserved in geological samples was in 1954 when Philip Abelson from the Carnegie Institute in Washington DC undertook chromatographic analysis of a number of fossil samples, including fossil fish more than 300 million years of age (from the Devonian Period) (Abelson 1954). Once the group switched to ion exchange chromatography, they noticed the presence of the nonbiological amino acid alloseucine (alle) in some fossil samples and speculated that this was perhaps the result of an age-dependent chemical reaction. Ed Hare from the same institute understood that the epimerization of Ile into alle was a potential tool for geochronology and that as epimerization is a chemical reaction governed by time and temperature, the levels of alle would increase in progressively older samples. This was demonstrated by the experiments of Hare and Mitterer (1969), who measured the rate of racemization of L-isoleucine to D-alloseucine in modern shell fragments heated at high temperatures; they then extrapolated these data to lower temperatures in order to estimate the rate of racemization of L-isoleucine in fossil shells to obtain what they believed to be an approximate age for these fossil shells.

This work blossomed in the 1960s with Ed Hare, Tom Hoering, John Wehmiller, Kenneth King Jr., Richard Mitterer, Sidney Fox, and Kaouru Harada, among others (see the *Mercenaria* Scientific Family Tree that was presented to Ed Hare in occasion of his retirement in 1998) rapidly expanding their range of analyses and substrates. The focus was primarily on understanding the processes and mechanisms of degradation: a range of studies on marine sediments, for example, exploited the stable thermal environment at the bottom of the sea in order to decouple the effects of age and temperature on the processes of racemization and therefore elucidate the kinetics of isoleucine epimerization (Wehmiller and Hare 1971; Bada and Schroeder 1972; Kvenvolden et al. 1973).

Almost in parallel at UC San Diego (SCRIPPS), Jeff Bada identified that aspartic acid was racemizing much more rapidly than isoleucine was epimerizing, offering an opportunity to date much younger fossils. Bada and coworkers applied this method to the dating of fossil bones and to the determination of past temperatures, by measuring the extent of racemization in several radiocarbon-dated bones. Hare worried that bone lost proteins too rapidly to be reliable, but so (to a lesser extent) did shell (Wehmiller 1977; Masters and Bada 1977, 1978; Miller and Hare 1980; Hare 1988). High profile studies, while the method was still under development (the sites of Boxgrove (Bowen and Sykes 1994); and del Mar (Bada et al. 1974, 1984)), resulted in controversial age estimates which led to a loss of support to the technique in parts of the community (Marshall 1990).

Studies on the mechanisms of racemization and pioneering applications of the method to archaeological and geological contexts (including meteorites, e.g., Engel and Nagy 1982) continued through the 1980s, the 1990s, and the 2000s. The application of AAR dating was mainly as a relative dating tool to identify the age of different geological deposits: aminostratigraphy (Miller et al. 1979). Research in this area continued, driven by a small number of groups, mainly in the USA, for example, Giff Miller, Darrel Kaufmann, and Glen Goodfriend working in the high Arctic and elsewhere (Miller et al. 1983; Goodfriend 1991, 1992; Kaufman and Brigham-Grette 1993; Kaufman and Sejrup 1995; Goodfriend et al. 1996) and John Wehmiller dating shell horizons along the east and west coasts of the USA (Wehmiller et al. 1977, 1995; Wehmiller 1982, 2013; Kennedy et al. 1982; Rockwell 1992) and South America (Hsu et al. 1989; Rutter et al. 1989). Datasets were also accumulated for China (Oches and McCoy 2001), Australia (Murray-Wallace and Kimber 1987; Murray-Wallace et al. 1993; Miller et al. 1997, 2005), Africa (Brooks et al. 1990; Miller et al. 1999), the Mediterranean (e.g., Hearty et al. 1986), Great Britain and the North Sea (Bowen et al. 1985, 1988; Bates 1993; Meijer and Cleveringa 2009). Many of these datasets are publicly available through the NOAA website, where additional citations can be found, as well as maps showing the scale of some of these AAR investigations. During the same years, scientists such as Ritz-Timme and Ohtani were using the method as a forensic technique to estimate the age of tooth dentine (Ohtani and Yamamoto 1991; Ritz-Timme et al. 2000).

The next turning point in research would then occur when two fields of research, which had been proceeding somewhat in parallel throughout the twentieth century, finally met: studies on protein-induced mineralization of hard tissues and studies on protein diagenesis. This led to the rationalization of the key concepts of intercrystalline versus intracrystalline proteins in biominerals.

Key Concepts

In considering the fate of amino acids in biominerals, it is helpful to operationally define two pools of constituent proteins, inter- and intracrystalline.

Intercrystalline

The intercrystalline fraction is defined as the components which are destroyed by chemical treatment, occasionally reduction with hydrazine (N_2H_4), usually oxidation with sodium hypochlorite, NaOCl (Sykes et al. 1995). As the latter is far more common, this will form the basis of subsequent discussion. The ability to destroy the organic matter implies that it occupies interstices in the biomineral between major contiguous blocks, such that they form a connected network (Suzuki et al. 2011). In biominerals with microcrystals (e.g., bone), all proteins are intercrystalline, as the individual mineral elements are too small to encapsulate proteins. In the case of bone, proteins may be entrapped in mineral aggregates (Salamon et al. 2005), but this has not yet been the focus of geochronological studies.

Intracrystalline

The intracrystalline fraction is that which survives prolonged oxidation/reduction. Since the definition is operational, it leads to a number of issues: the concentration of the oxidant, the duration of the treatment, and the optimal particle size need to be tested for each biominerals. Prolonged exposure to bleach causes a slow but steady decline in amino acid concentrations and an increase in racemization, indicating that the system is not perfectly isolated. The operational definition usually refers to crushed biomineral (around 500 μm particle size) exposed to 12 % wt/vol NaOCl for 48 h (Penkman

et al. 2008). The effect of oxidation with NaOCl (bleaching) is shown schematically in Fig. 2: the bleach removes the intercrystalline proteins, more prone to contamination and interaction/exchange with the environment. The protected intracrystalline fraction contains both the original proteins and their degradation products. This enables the quantification of the extent of protein breakdown occurring via different reactions: peptide bond hydrolysis and amino acid racemization and decomposition (e.g., dehydration of the amino acid Ser to Ala).

Within the intercrystalline fraction, the extent of retention of amino acids will be a function of the degree of protein breakdown, the rate of loss from the sample, and any contribution from the burial environment itself. Therefore, there will be a broad correlation between the age of the sample and the extent of racemization, and local burial conditions will dictate the overall value. The intracrystalline fraction should behave in a more predictable fashion (Sykes et al. 1995). In the burial environment, the intercrystalline proteins are often lost quickly, and therefore, many past studies that were analyzing whole-shell proteins were *effectively* analyzing the intracrystalline fraction. Therefore, the isolation of this fraction through chemical pretreatment is more important for samples with a short burial history. The added advantage of bleaching is the removal of external contaminants, e.g., exogenous amino acids. However, the effectiveness of bleaching needs to be tested for each

Fig. 2 A strong oxidation treatment is able to remove the intercrystalline protein from biominerals, leaving behind a fraction of the original proteins, degraded in situ (effectively, in a closed-system environment)

biomineral: for example, the isolation of the intracrystalline proteins from the chitin-rich ostracod valves has been shown to be not straightforward (Bright and Kaufman 2011). Nonetheless, the conceptualization of the intracrystalline fraction has added a further piece to the jigsaw, along with other experimental evidence on the behavior of proteins in biominerals (high-temperature experiments, intergeneric comparisons, and diagenetic models, e.g., Wehmiller 1980; Mitterer and Kriausakul 1984). Subsequent discussion will refer to racemization analysis of the intracrystalline fraction, unless otherwise explicitly stated.

The Life and Death of a Protein: From Biomineralization to Breakdown

Although the presence of water trapped in mollusk shell carbonates had already been noted (Hudson 1967), for many years, the idea of the intracrystalline proteins seemed to make little sense, even when the first detection of organic material and water trapped within the crystals was reported: a so-called “frothy” structure in single crystals of *Mytilus* nacre (mother-of-pearl) was observed by transmission electron microscopy (TEM; Towe and Thompson 1972).

Why are proteins trapped inside crystals? Decades of research in biomineralization is starting to unveil the process of entrapment of proteins within biominerals. Fast-forming systems, such as eggshell, retain higher concentrations of amino acids in the intracrystalline fraction than slow-forming systems, for example, mollusk shells, and therefore in part incorporation may be kinetically driven. Ostrich eggshell retains ~30 nmol amino acids per mg mineral after bleaching; limpet shells (*Patella vulgata*) a mere ~4 nmol per mg. However, both biominerals contain ~50 nmol amino acids per mg of unbleached (i.e., intracrystalline + intercrystalline) biomineral (Crisp et al. 2013; Demarchi et al. 2013a). Importantly, the intracrystalline proteins and, generally, proteins in biominerals display a wide range of amino acid sequences and three-dimensional structures (these can be found in the NCBI database).

Proteins promote and regulate biomineralization. The model proposed for the chicken eggshell protein ovocleidin-17 (OC-17) (Freeman et al. 2010) highlights the role of Arg-rich domains of the protein and their action as “clamps” that bind calcium and promote the transformation from amorphous calcium carbonate (ACC) to crystalline mineral. If these crystallites aggregate to form mesocrystals (Cölfen and Antonietti 2005), it is easy to envisage how the protein becomes surrounded and entrapped. However, even in situations in which the protein does not act as a catalyst, other authors have proposed models where remnant proteins are overgrown into the mineral (Li et al. 2011; Okumura et al. 2013). The role of these in modifying the structural properties of the mineral is now indeed an active area of research (e.g., Okumura et al. 2013).

Whole-genome sequencing and targeted analysis, such as by immunohistochemistry, are beginning to reveal the differences in the character of proteins found in biominerals, and the new sequences and new tools for analysis are rapidly accelerating knowledge of these systems. One example is the intriguing set of glycine-asparagine (Gly-Asn or, in one-letter code, GN) repeats found in the sequence of the protein N16.1 isolated from the intracrystalline fraction of the mollusk *Pinctada fucata* (see Table 1).

The Gly-Asn repeat is highly unstable and degradation rates depend upon environmental temperature; therefore, this might suggest that variants of this organism which are biomineralizing at different conditions (e.g., water temperatures) might have evolved a system whereby they increase the number of the GN repeats to enhance the stability of the protein. From this brief review, it is evident that we are only beginning to understand the role played by the intracrystalline fraction; some may be accidental overgrowth, others may be trapped catalysts, while still others may be

Table 1 Gly-Asn repeats are found in the sequence of intracrystalline proteins isolated from *Pinctada*

playing a functional role, perhaps even acting as remote triggers controlling later-phase processes. What we are beginning to understand is that the entrapped intracrystalline proteins are not homogeneous and it is therefore not surprising that their rates of decomposition (and thus their rate of racemization) will vary from species to species and ultrastructure to ultrastructure, the so-called species effect (Lajoie et al. 1980; Wehmiller 1980), which is widely observed in AAR. Indeed, many whole-shell AAR studies recognized the presence of different peptide fractions, some more refractory than others (e.g., Kaufman and Sejrup 1995), and this was used as a tool for taxonomic identification (Andrews et al. 1985; Wehmiller 1989; Kaufman et al. 1992). What is more surprising is perhaps the fact that the species effect is preserved within the intracrystalline fraction and a common “template” cannot be found, although these proteins are likely to be directly involved in the interaction with the mineral phase.

Death and Diagenesis

After deposition, organic remains are in thermodynamic disequilibrium with their environment and they will attempt to reach equilibrium with the surrounding environment. The sequence of intermediate metastable conditions is defined as a series of diagenetic pathways or diagenetic trajectories (Wilson and Pollard 2002). Several difficulties arise in defining these for protein diagenesis, even when looking at the intracrystalline fraction, because (a) the actual amino acid sequence (and composition) for most proteins is unknown and (b) the temperature sensitivities of each of the reactions within the network of reactions driving the overall diagenesis are difficult to assess. Therefore, a “black box” approach is used in protein diagenesis studies, where three main reactions, occurring simultaneously, are tracked, as they can provide information on the time elapsed since degradation started, i.e., the time of death of an organism.

Hydrolysis

Peptide bonds are inherently unstable and will undergo hydrolysis, the rate depending upon a number of factors: the pH of the solution, the presence of catalysts, the availability of water (which is consumed in the reaction), and the steric constraints upon the bond. One advantage of the

Fig. 3 Mechanism of dipeptide hydrolysis

intracrystalline fraction is that all of the above factors should be equivalent in the tissues of the same taxon.

Hydrolysis breaks the peptide bonds, yielding progressively shorter peptides until only the basic building blocks, the free (as opposed to peptide-bound) amino acid residues, are present. Hydrolysis requires the presence of chemically available water (Fig. 3), which must be present in the intracrystalline fraction, since (a) we observe the rapid release of amino acids from the peptide-bound fraction into the free amino acid pool due to peptide bond hydrolysis and (b) it has been directly observed within crystallites (Hudson 1967; Gaffey 1988). Furthermore, diagenetic decomposition of hydroxy amino acids, Ser, Thr, and Glu (Bada et al. 1978; Walton 1998), and carbohydrates (Collins et al. 1992) would increase the amount of water available for hydrolysis of the intracrystalline proteins. However, a residual un-hydrolyzed fraction is usually found within the intracrystalline fraction of different biominerals; Collins and Riley (2000) speculated that this could be due either to a reduction in the availability of water or to the presence of a recalcitrant pool of amino acids.

Each protein possesses a unique primary structure and contains a wide variety of peptide bonds of different strengths. However, hydrolysis exhibits a certain degree of specificity, and in the natural environment, under mild pH and temperature conditions, three main mechanisms of hydrolysis are likely to occur (Bada 1991):

1. Cleavage of internal peptide bonds, which is rapid for Ser, Ala, Gly, and Thr and slowest for Val and Ile.
2. Internal aminolysis at the N-terminus, yielding diketopiperazine (cyclic dipeptides); this is more rapid than internal cleavage for small peptides made up of hydrophobic amino acids and at neutral pH. The importance of this reaction therefore increases with increasing extent of diagenesis.
3. Hydrolysis of an amino acid at the C-terminus, which is acid/base catalyzed but is independent of pH between pH 5 and 9 (Kahne and Still 1988). The importance of this reaction also increases with proceeding diagenesis.

The overall extent of hydrolysis in fossil biominerals is a useful proxy of the age of the sample and can be easily quantified as the percentage of free amino acids (FAA) over the total hydrolyzable amino acids (THAA): $\% \text{FAA} = [\text{FAA}]/[\text{THAA}] \times 100$.

The temperature sensitivity of peptide bond hydrolysis is dependent on the relative stability of the bonds between pairs of amino acids; overall, studies into the extent of hydrolysis at high temperature (during laboratory simulations of diagenesis or kinetic experiments) have shown that, generally, the apparent activation energy for hydrolysis is lower than for racemization (Crisp et al. 2013; Demarchi et al. 2013b; Tomiak et al. 2013). This implies that at lower (burial) temperatures, hydrolysis will be favored over racemization and that therefore hydrolysis represents the rate-limiting pathway for overall diagenesis. Indeed, hydrolysis is a key reaction step in racemization as it generates N-terminal residues, and these are the most prone to undergo racemization (Fig. 4).

Fig. 4 Schematic mechanism of peptide bond hydrolysis at the N-terminus, promoting fast racemization of amino acids (AA) that are released in the free pool

Fig. 5 Proposed mechanism of racemization of free amino acids, via a carbanion intermediate

Racemization

An amino acid can exist in one of four states: (a) entirely bound within a peptide chain, (b) at the N-terminus, (c) at the C-terminus, or (d) as a free amino acid. This influences its ability to undergo racemization.

Free Amino Acids

The main focus of attention has traditionally been on the mechanisms of racemization of free amino acids in aqueous solution; Neuberger (1948) proposed that abstraction of the hydrogen linked to the central carbon leads to the collapse of the tetrahedral geometry of the amino acid and the formation of a planar carbanion. This is equally likely to be attacked by a proton from either direction, with the possibility of umbrella-like inversion of the tetrahedron, thus regenerating the L-form or producing the D-enantiomers (Fig. 5). The rate-limiting step of the reaction is therefore the abstraction of the proton. Increasing the electron-withdrawing and resonance-stabilizing capacities of the substituents attached to the central carbon of an amino acid causes a corresponding increase in the racemization rate (Bada and Schroeder 1975). The mechanism is applicable not only to free amino acids but also to amino acids bound in peptides and proteins: if the amino group is protonated (as it would be at an N-terminal position), then it is able to participate in resonance, facilitating the loss of the hydrogen.

Different amino acids display different relative racemization rates: since racemization is enhanced by species which are able to stabilize the carbanion intermediate, a major role is played by the –R group. For example, amino acids that have –R groups which are highly electron withdrawing (e.g., Ser) should have the fastest racemization rates at neutral pH, while those which have substituents that are electron donating (e.g., Val) should have the slowest rates (Bada 1985). Since the –R group is amino acid specific, each amino acid is characterized by a different value of enthalpy and entropy, which reflect the electronic and steric factors determining racemization rates for free amino acids in aqueous solution. Although different factors enhance or retard the racemization rates, racemization of free amino acids in aqueous solution has generally been found to obey first-order reversible kinetics (Bada and Schroeder 1975):

$$\ln[(1 + D/L)/(1 - D/L)] - \text{constant} = 2kt \text{ (for amino acids with one chiral centre)}$$

$$\ln[(1 + A/I)/(1 - K'(A/I))] - \text{constant} = (1 + K')k_{\text{Ile}}t \text{ (for Ile)}$$

where t is time and the constant term is different from zero as it represents the small amount of D-enantiomer produced during sample preparation; $K' = 1/K_{\text{eq}}$ and K_{eq} is the equilibrium alloisoleucine/isoleucine (A/I) ratio, which is ~1.3 to 1.4 (Bada and Schroeder 1975).

These equations can be used for deriving the racemization rate of a given free amino acid in aqueous solution at a known temperature. Typically, kinetic experiments are conducted at three (or more) different temperatures and the increase in D/L value monitored over time. When the experimentally derived $\ln [(1 + D/L)/(1 - D/L)]$ is plotted against the time of isothermal heating, if the reaction is first order, then a linear relationship is found, of slope $2k$. The intercept represents the constant value, i.e., the preparation-induced racemization. The racemization rates obtained at the three (or more) temperature points can then be used for extrapolating the racemization rate at any temperature. This is possible because the reaction rate and the temperature are directly related in the Arrhenius relationship:

$$k = Ae^{(-E_a/RT)}$$

where k is the rate constant, A is the frequency factor (year^{-1}), E_a is the activation energy (kJ/mol or kcal/mol), R is the gas constant (0.001987 kcal/mol or 0.008314 kJ/mol), and T is the absolute temperature (degrees Kelvin, K). A plot of the natural logarithm of k versus $1/T$ yields a straight line of slope E_a .

In the real world the situation is more complex, because unlike free amino acids, the extent of racemization is a consequence of a number of reactions, notably hydrolysis and racemization, with different temperature dependencies, which means that net racemization rates are unlikely to display a perfect linear relationship with temperature. By estimating the activation energy and the frequency factor, the racemization rate at the burial temperature for fossil samples of unknown age can be approximated. The temperature value used for fossil samples is the “effective diagenetic temperature” (EDT; see “► [Amino Acid Racemization, Paleoclimate](#)”) representing the integrated effect of all temperatures to which the samples at a given depth have been exposed (Wehmiller 1977).

Bound Amino Acids

Racemization of peptide-bound amino acids occurs via complex pathways, which have not yet been fully clarified. The body of knowledge acquired in the past decades by experimenting on both synthetic peptides and biominerals has allowed building a general model (Wehmiller 1980; Mitterer

and Kriausakul 1984) whereby it is postulated that peptide-bound amino acids are unable to racemize until progressive hydrolysis drives them to a terminal position (Fig. 4). However, exceptions to this general rule are the fast in-chain racemization of Asn and Asp (Geiger and Clarke 1987) and Ser (Demarchi et al. 2013c) and the accelerated rate of racemization in diketopiperazines (Steinberg and Bada 1981) at the peptide chain C-terminus. In general, the rate of amino acid racemization within a protein retained in a closed system depends on (a) the temperature of the environment (or of the experiment), (b) the availability of water for peptide bond hydrolysis, (c) the position of the amino acid within the protein sequence throughout diagenesis, and (d) the three-dimensional structure of the protein.

Therefore, kinetic relationships derived from high-temperature experiments are unable to capture the underlying chemical rationale of the mechanisms involved in peptide-bound amino acid racemization. Mathematical expressions have been developed that enable the calculation of *apparent* racemization rates and the assessment of the temperature dependence of the reactions and, ultimately, the extrapolation of an absolute age. These equations (first order, parabolic, power transformations; Clarke and Murray-Wallace 2006) are usually derived from high-temperature experiments on biocarbonates, and these can be further constrained by the measurement of racemization in samples of well-defined age, for example, on radiocarbon-dated shells. This then allows building a calibrated age equation (e.g., Kosnik et al. 2008, 2013) that can be used effectively to derive age since death for subfossil biominerals. This is important, as studies on the intracrystalline fractions of avian eggshell, mollusk shells and corals have shown clearly that the pathways of diagenesis at high temperature may not necessarily be the same as those at low temperatures (Crisp et al. 2013; Demarchi et al. 2013b; Tomiak et al. 2013); therefore, the age-racemization relationship must be calibrated for samples of known age and where the effective diagenetic temperature can be reconstructed (e.g., foraminifera from deep-sea cores). This is further confirmed by the recent study of Allen et al. (2013), who fitted a variety of different functions to racemization data and observed that high-temperature and field data behave differently. In part, this is because the relatively high activation energies (~120 kJ/mol) mean that unless the temperature range is very narrow, data usually covers different stages within the decomposition pathway. Because of this, an alternative approach, which estimates rate differences simply by relative scaling, has been proposed (the so-called “model-free” approach; Crisp et al. 2013; Demarchi et al. 2013b; Tomiak et al. 2013).

The temperature sensitivity of the reaction is especially important when considering the calibration of samples over Pleistocene timescales: temperature fluctuations affect the rates of racemization, and therefore, the succession of glacial and interglacial stages needs to be considered (a recent example of combining kinetic models and age calibration (by $^{87}\text{Sr}/^{86}\text{Sr}$) over the Quaternary is the study by Wehmiller and colleagues (2012) in the US mid-Atlantic Coastal Plain).

Methodology

Sample Types

In order to use a substrate for dating, the researcher has to be confident that the material will prove suitable, i.e., that the biominerals will have retained its original proteins. These would have been degrading at a certain rate, depending upon the proteins themselves (and therefore the species effect; Lajoie et al. 1980), the pH of the environment, and the burial temperature. Biominerals, such as eggshell, mollusk shells, foraminifera, brachiopods, ostracods, corals, and tooth enamel, are all good substrates for AAR dating.

When looking at intracrystalline proteins, the most common problem associated with AAR dating is that the system is partially reset if the biomineral undergoes diagenetic alteration, resulting in the opening up of a previously closed system. Due to the difficulty of identifying diagenetic transformation from aragonite to calcite, the latter biomineral is favored. A comparison of the aragonitic shells and calcitic opercula of *Bithynia tentaculata* (and *Bithynia troschelii*) highlighted the limitations with the former: in the case of the calcitic opercula, some samples displayed evidence of distortion and recrystallization, and these too displayed atypical patterns of racemization (Penkman et al. 2007, 2013). However, this does not mean that aragonitic shells should not be used: the presence and extent of diagenetic alterations can be characterized by microscopical observations and techniques such as X-ray diffraction, and the use of multiple samples of different taxa is important for recognizing aberrant results.

Sample Collection

The best way to collect samples for AAR is to collect as many as reasonable, to note all information available and, whenever possible, to define the sampling strategy with the scientists in charge of the excavation of the site. Details on sample collection strategies can be found in many studies and are summarized in Wehmiller and Miller (2000). If collecting in the field, note the depositional environment and the position of the specimens, especially when dealing with high-energy depositional environments, with high likelihood of age mixing (e.g., Wehmiller et al. 1995; Krause et al. 2010).

If collecting from a museum, the information on sample collection and storage may not always be available. This is important because one of the major issues to be taken into account is whether the samples have been exposed to conditions that have impacted on their thermal history, increasing the levels of racemization: for example, drying in an oven or exposure to heat during shallow burial. If possible, avoid sampling from the surface of an outcrop, but target instead samples that are buried under at least 1 m of sediments (or at a depth where the seasonal temperature variations are dampened to less than 6 °C (Wehmiller and Miller 2000)). Burning and heating, especially for edible mollusks or eggshells, should also be taken into account when collecting samples from archaeological sites, e.g., shell middens, or cave deposits in proximity to hearths. Some useful “burning indicators” can be identified on the basis of the bulk amino acid composition and the covariance of D/L values of different amino acids (e.g., Brooks et al. 1991; Miller et al 1999; Demarchi et al 2011; Crisp 2013).

Due to the intergeneric differences in racemization rates, aminostratigraphies can only be built for monogeneric samples; therefore, whenever possible sample multiple taxa from each geological or archaeological unit. At least five individual samples should be taken from each depositional horizon (in both geological and archaeological settings) and taxon, in order to assess the natural variability (Miller and Brigham-Grette 1989) within the taxon and the site.

How Can Amino Acid Racemization Be Measured?

Any mixture of analytes needs to be separated into its individual components in order to achieve quantification. The classic separation technique for complex mixtures is chromatography. Analysis of chiral amino acids is challenging, because the two molecules (L- and D-enantiomers) are only subtly different. Broadly, three different strategies have been used. Originally, diastereomers were measured using ion exchange chromatography, which could be followed by a variety of different (some very sensitive) detection methods. The method had the advantage of being robust, sufficiently

so for Ed Hare and his team to develop a system that could be taken to the field. However, it had one major disadvantage: it could only discriminate between the two diastereomers of isoleucine, one of the slowest-reacting amino acids.

A new method of gas chromatography (GC), first developed at NASA-Ames, became routinely used during the 1970s (see the first interlaboratory comparison study led by Wehmiller in 1984). This guaranteed very good separation of the constituent amino acids separated on a chiral stationary phase (column), and although more challenging than others, its extremely good separation of multiple amino acids has meant that GC methods are still used, notably by some forensic laboratories who demand the very best separation and resolution, for example, when assessing very low levels of racemization in young (forensic) samples (Ohtani and Yamamoto 1991; Ritz-Timme and Collins 2002).

In 1998 Kaufman and Manley published a key paper in which they used a chiral derivative (based upon chemistry previously developed by Brückner et al. (1991)) to separate nine enantiomeric pairs on a conventional HPLC (high-pressure liquid chromatography) reverse phase column (Kaufman and Manley 1998). This RP-HPLC method is very sensitive, paving the way for high-throughput applications of the technique; scientific AAR studies now commonly report hundreds of analyses. This is now the most widely applied method, although alternatives (e.g., UHPLC, ultrahigh-performance liquid chromatography) are being considered to enhance the sensitivity and the speed of the analyses, in order to further reduce sample size and increase throughput. Published interlaboratory comparison studies (Wehmiller 1984, 2013; Powell et al. 2013) detail the different characteristics of each method.

Present Investigations and Future Directions

If suitable samples and suitable separation techniques are used, AAR can be a very powerful dating tool. The most successful application of the technique is perhaps in assessing the age of microorganisms (e.g., foraminifera tests) in deep-sea cores, where the temperature is stable and the variability reduced (e.g., Müller 1984; Kaufman et al. 2008). In the Quaternary record, applications include building calibrated geochronological frameworks for the UK (e.g., Penkman et al. 2013) and sequences in the USA (e.g., Wehmiller 2013) and in the Mediterranean (e.g., Hearty et al. 1986). Great attention has been given to establishing long and precise sequences for the Holocene, e.g., in Australia (e.g., Kosnik et al. 2013). Calibration of the D/L values is obtained through radiocarbon, but advances in luminescence dating and cosmogenic nuclides dating are likely to be in the spotlight of research in the next decade.

Currently, AAR cannot be applied as a numerical method per se, because of a) uncertainties associated with the temperature history of each sample (especially for the Quaternary record at midlatitudes) and b) difficulties in assessing the kinetic parameters of each diagenesis reaction. Paleotemperature models are however becoming more and more sophisticated (see “► [Amino Acid Racemization, Paleoclimate](#)”) and are likely to offer the unprecedented opportunity of refining our understanding of the temperature- and age-driven diagenesis reactions. This, combined with growing information on protein sequence and structure, will likely transform the way AAR scientists think and apply the technique. A greater emphasis on interlaboratory trials (Wehmiller 1984; Powell et al. 2013; Wehmiller 2013) is further evidence of the growing maturity of the discipline.

Acknowledgments

We are truly indebted to two anonymous reviewers for their comments on this manuscript. Their insight in the earlier phases of development of the technique, which they were willing to share with us, has been of invaluable help in compiling this review. The responsibility for any errors or inaccuracies still present is entirely ours.

Kirsty Penkman and the AAR group in York are thanked for their help, support, and discussion over the years.

Amino Acid Racemization, Paleoclimate

Matthew Collins* and Beatrice Demarchi

BioArCh, Department of Archaeology, University of York, York, UK

Definitions

Amino acid racemization (AAR): changes in the chirality of amino acids, the building blocks of proteins, resulting from the time-and-temperature-driven breakdown of proteins. AAR is used in the geosciences as a relative dating technique, typically comparing the ratio of D/L amino acid enantiomers in biominerals.

Paleoclimate: the complex interrelated changes brought upon by temperature shifts caused by orbital forcing of the geosphere, hydrosphere, atmosphere, biosphere, and anthroposphere throughout Earth's history.

Introduction

The level of racemization in any one sample is in effect a measure of the integrated time/temperature history (thermal age) that accounts for the observed degree of protein diagenesis. Therefore the contribution of amino acid racemization (AAR) to understanding past climate changes is twofold: it can be used either as a geochronological tool, to reconstruct the timing of major climatic events, or (less commonly) as a paleothermometer in the case of samples of known age, because the higher the observed rate of racemization (k , see Arrhenius plot in Fig. 1), the warmer the burial history.

Dating Past Climate Cycles

AAR geochronology can help to clarify the timing of past climatic cycles and the extent of the environmental responses to these changes, from a local to a global scale. One of the most successful applications is the identification of interglacial episodes in the patchy terrestrial sedimentary record, which can thus be linked to the global temperature fluctuations recorded in ocean and ice cores (Oxygen Isotope Stages or Marine Isotope Stages). This is particularly effective at high latitudes, where cyclic fluctuations in global temperature have resulted in the accumulation of sediments typically during warm ice-free periods; here AAR can help to assign these deposits to specific climate cycles (Penkman et al. 2013). In these and in other midlatitude regions, models have been developed that link the acceleration of the racemization rates to interglacial temperature increase and sea-level highstands (e.g., Hearty et al. 1986).

Fig. 1 Increase in the extent of racemization as an effect of time and temperature, e.g., throughout the last glacial/interglacial cycle

Paleothermometry

The rates of protein decomposition (diagenesis) increase exponentially with temperature. Effective burial temperature (T_{eff} , also known as the effective diagenetic temperature or EDT (Wehmiller 1977)) is the temperature inferred from rate constants determined in dated samples (Fig. 1). This is influenced by (i) seasonal temperature fluctuations (which increase with distance from the equator but are dampened with burial depth and shading) and (ii) long-term changes in global temperature.

Paleothermometry and AAR are therefore inextricably entwined. Accurate age estimates can be obtained on the basis of D/L values, when the temperature history (T_{eff}) of a sample is known; conversely, when the absolute ages of the sample are known, T_{eff} can be calculated. In both cases the kinetic parameters of the reaction must be established (usually estimated from higher temperatures using an Arrhenius plot; see Fig. 1). Age estimations are more likely to be more accurate where the extent of seasonal fluctuation is minimized (e.g., sediment cores), since near-surface sediments (especially deposits of anthropogenic origin, e.g., shell middens) may experience short-lived periods of extreme temperature.

The accuracy of the estimates of the kinetic parameters affects these calculations (McCoy 1987); kinetic models based on high-temperature (artificial) diagenesis (Fig. 1, Arrhenius plot) can only be constrained to the “real” burial temperatures using samples that can accurately be dated by independent means. This is often done using radiocarbon, hence covering the Holocene and Marine Isotope Stages 2 and 3. The disparity between Holocene T_{eff} and that of the sample can be used to estimate changes in paleotemperature (ΔT) at the site, for example, to quantify the extent of cooling during the Last Glacial (e.g., Miller et al. 1987, 1997). If multiple samples of known age are

available, it is then possible to impute a paleotemperature record, but only relatively few attempts have been made to do this due to the need for long, high-resolution chronologies (Kaufman 2003).

Conclusions

Individual biominerals can be considered as temperature loggers which report a single (integrated) thermal age. Improvements in our ability to model paleotemperature mean that in the future it should be possible to predict the thermal history of a specific site at a specific burial depth; an example where this is being attempted is the <http://thermal-age.eu> website. When combined with good kinetic estimates of protein decomposition, it may be possible to use such models to estimate the absolute age of a sample from AAR (or indeed other temperature dependent data, such as hydration of silicates).

Laser Ablation Inductively Coupled Mass Spectrometer (LA ICP-MS)

Paul Sylvester*

Department of Geosciences, Texas Tech University, Lubbock, TX, USA

Laser ablation inductively coupled plasma mass spectrometer (LA-ICP-MS) is an in situ analytical instrument that is used for determining the elemental and isotopic composition of micrometer-sized areas of solid materials such as minerals, glasses, metal alloys, bones, teeth, calcareous shell and wood, and fluids trapped as inclusions within solids (Sylvester 2008). A laser ablation system is connected to an inductively coupled plasma mass spectrometer. Laser pulses remove small volumes of the sample, typically from pits that are 30–50 μm wide and deep, during 1–2 min of ablation. The ablated aerosols are transported in a carrier gas stream to the ICP and converted to ions, which can be separated based on their mass to charge ratios by a mass spectrometer and measured with a detector. The ICP is hot ionized argon gas produced at the tip of a glass torch by an intense electromagnetic field generated by an oscillating current in a water-cooled copper coil wrapped around the glass torch (Linge and Jarvis 2009). Most commonly, the mass spectrometer consists of a quadrupole mass filter or a magnetic sector field mass analyzer incorporating single or multiple collectors (MC). The detector in single-collector instruments is typically a secondary electron multiplier, whereas multiple Faraday cups can be used in MC devices. The moderate capital cost, robust design, multielement capability, short analysis times, minimal sample preparation requirements, and good precision and accuracy of LA-ICP-MS compared to competing techniques for in situ micrometer-scale, chemical analysis have led to its widespread use in university, government, and industry research laboratories worldwide.

For analysis, the sample surface is commonly prepared as a thin polished slice or slab, and imaged using optical light or scanning electron microscopy, in order to select areas appropriate for laser sampling. The sample is ablated in an airtight sample cell flushed with helium gas to transport the ablated aerosols through plastic tubing to the ICP. Ablation is usually carried out using a nanosecond pulsed laser, emitting ultraviolet light, which is absorbed more completely than infrared light by many minerals and other materials, particularly those that are transparent or poor in iron. Most modern systems are based on a neodymium-doped yttrium aluminum garnet (Nd:YAG) solid-state laser using the frequency-quintupled 213 nm output or an argon-fluoride (ArF) excimer gas laser using its fundamental 193 nm wavelength. Recently, femtosecond pulsed lasers have been shown to produce aerosols with smaller particle sizes and negligible sample melting at the ablation site, improving analytical performance (Shaheen et al. 2012).

LA-ICP-MS is used for scientific dating largely by measuring the ages of minerals containing uranium or thorium, which decay to radiogenic isotopes of lead. Zircon is the mineral dated most commonly using the technique, although U-Th-Pb ages for other minerals, such as monazite, baddeleyite, allanite, apatite, rutile, and titanite are increasingly reported. Minerals with ages from as young as about a million years to those that comprise the oldest known material found in meteorites can be dated by LA-ICP-MS using the U-Th-Pb method. Ages are commonly reported with uncertainties of 1 % or less, but interlaboratory comparisons have documented biases of about 2 % (Košler et al. 2013). The major source of error in U-Th-Pb dating by LA-ICP-MS is inaccurate

*Email: pjsylvester@gmail.com

*Email: psylvester@mun.ca

correction for laser-induced fractionation of more-volatile Pb relative to more-refractory U and Th. U-Th/Pb fractionation is matrix dependent and is affected by variations in laser sampling as a function of mineral composition, color, crystallinity, and fracturing. Various procedures are employed to limit U-Th/Pb fractionation including matching calibration standards to the matrix of the unknowns, ablating with lasers emitting deep ultraviolet (193 nm) light or femtosecond pulses, moving the sample beneath the laser beam (referred to as raster or scan mode) to limit the depth of ablation, and various mathematical corrections.

Dendrochronology, Fire Regimes

Peter M. Brown*

Rocky Mountain Tree-Ring Research, Inc., Fort Collins, CO, USA

Definition

Use of tree-ring data and methods to reconstruct past fire timing, fire regimes, and fire effects on individuals, communities, and ecosystems.

Introduction

Fire directly or indirectly affects woody plants in many ways, some of which will leave evidence in age or growth patterns in individual trees or community structure that can be cross-dated using dendrochronological methods. This evidence can be used to reconstruct past fire dates, fire regimes, and fire effects on individuals, communities, and ecosystems (“pyrodendroecology”). Fire regimes are defined as the combination of fire frequency, severity, size, seasonality, and relationships with forcing factors such as climate or changes in human land use.

Fire Evidence in Trees and Community Structure

A common type of fire evidence is from severe fire that kills all or most trees in an area which opens up space for new trees to establish. Even-aged forest structure is often used as evidence of past lethal fire, also referred to as “stand-replacing” fire. Such evidence provides a minimum date for the fire (i.e., the fire occurred sometime before the innermost dates of the oldest trees), and, by sampling multiple stands in an area, estimates of the fire size can be made based on broader-scale patterns of tree ages. Conversely, multiaged structure is considered to be evidence of less severe fires or other patchy mortality and recruitment events. Note that a dating limitation to age structure studies is that rarely are total tree ages able to be reconstructed. Tree ages are usually derived from increment cores or cross sections collected at a height above and several years after the date of seedling germination. Often cores or sections for age structure studies are collected low on the tree bole (e.g., 10–30 cm above ground level), and some studies have applied a correction factor to estimate germination dates from sample-height pith dates. However, regardless of these methods, generally age structure data are not accurate to exact years of tree germination.

Another commonly used line of evidence of past fire is from fire scars (Fig. 1). Fire scars are areas of cambial mortality resulting mainly from lower intensity fires that burn through surface fuels such as leaf litter, grasses and other herbaceous plants, or shrubs. If the cambium is killed all the way around the tree circumference, the tree is girdled and dies. However, if only a portion of the cambium is killed, a fire scar is formed and the tree continues to live. The formation of a fire scar is

*Email: pmb@rmtr.org

Fig. 1 (Left) A *Pinus ponderosa* stump with a fire-created “catface” facing to the right. The catface was formed from repeated fire scars (visible as distinct ridges inside the catface). Bark and sapwood have eroded from the outside of the stump, and only the heartwood is left. The stump was cut with a crosscut saw, placing the date of cutting likely in the late nineteenth or early twentieth century before widespread use of motorized chainsaws. (Right) Cross-section sample cut with a chainsaw from a fire-scarred *P. ponderosa* snag (standing dead tree). Dates of fire scars are marked on the section. The tree died in 1916 from a bark beetle attack as evidenced by blue stain in the small remnant of sapwood visible at the top of the photograph. Most of the sapwood has decayed since the tree died, limiting the amount of time that a death date could be established (Photograph credits: P. M. Brown)

a function of both bark thickness (thicker bark helps to insulate the cambium) and the intensity of the fire (a certain temperature is necessary to kill the cambium through the bark). After scar formation, circumferential growth will continue from the margins of the dead cambial zone, often completely regrowing over the scar unless the area is burned again in a subsequent fire (Smith and Sutherland 2001). After a tree has been scarred once, rapidly growing woundwood on the scar margins tends to have thinner bark making it more susceptible to subsequent fires. Because of this susceptibility, long sequences of multiple fire scars are often found on trees in forested ecosystems that experienced frequent, episodic, low intensity fires, such as many dry *Pinus* ecosystems around the world (Falk et al. 2011; Fig. 1 right).

Fire scars can usually be dated to their exact year of formation within a cross-dated ring series. Fire frequency is derived from sequences of composited fire-scar records found on multiple trees in a stand or study area. Seasonality of burning also can be estimated from the position of the scar within the annual ring and knowledge of the general seasonal timing of cambial growth for a species and location. The presence of a fire scar on a tree implies that the fire that formed it was relatively low intensity and nonlethal, at least at the scale of the individual tree. By compiling dates of fire scars from multiple trees or plots across a landscape, the relative sizes and severities of past fires can be estimated with a great deal of accuracy (Farris et al. 2010). Increasingly, fire history studies use both tree age structure and fire-scar data to develop more complete estimates of the frequency and patterns of lethal and nonlethal burning across a study area (Brown et al. 2008). Furthermore, the accuracy of annual fire dates provided through dendrochronological cross-dating permits comparison of fire timing between sites, mountain ranges, and regions and with independently derived tree-ring reconstructions of climate variables (Swetnam and Brown 2010).

Important insights into historical fire climatology have been made owing to the accuracy of fire dates provided through regional networks of fire-scar records (Falk et al. 2011).

Other evidence of fires recorded by trees includes tree death dates and tree growth responses. Trees killed by fire can be dated by cross-dating with living trees. However, sapwood typically does not last very long after a tree is dead (even on standing dead trees, sapwood lasts at most a few decades; Fig. 1 left), which limits the length of time that this line of evidence can be used to reconstruct fire-caused mortality. Growth responses include abrupt growth suppressions or releases. For example, a growth suppression may occur after a fire as a result of severe scorching of a tree canopy. A growth release may occur as a result of neighboring trees being killed with a subsequent loss of competitive pressure on the surviving tree. Other responses include traumatic resin ducts or other ring features that indicate injury to the tree (Brown and Swetnam 1994).

A note of caution is warranted here, in that many other environmental factors may leave similar evidence in trees as those resulting from the effects of fire. For example, lightning and other injury events may partially kill the cambium and leave a scar in the ring series. The approach used by most studies has been to composite potential fire evidence from multiple trees in a stand or study area and depend on synchronous patterns as indications of fire timing and effects. For example, lightning will result in a scar on only a single tree in any given year, whereas fire scars will be recorded on several trees in the same year due to the spreading nature of fire within a stand of trees. Conversely, not all fires that burn at the base of a tree will leave a fire scar or other fire-caused evidence, and again compositing evidence from multiple trees is a usual step to compile more complete spatio-temporal fire histories (e.g., Farris et al. 2010). Dendrochronological cross-dating is, of course, crucial in these studies to provide absolute calendrical dates for fire evidence to assess synchronous or asynchronous patterns within and between trees, sites, or regions.

Application of Dendrochronological Fire Regime Studies

Studies using pyrodendroecological data have generally had three broad and often overlapping goals: (1) to document and characterize past fire effects on ecosystem processes, structure, and function across spatiotemporal scales; (2) to understand how fire regimes have been affected by forcing factors such as temporal or spatial changes in climate, human land use, and vegetation (fuel) structure; and (3) to develop historical information used in forest and ecosystem management. Pyrodendroecological data provide understanding of fire as an ecological process over periods longer than those available from typical ecological studies or even instrumental or observational records. For example, a major focus of many pyrodendroecological studies has been to examine longer-term (multi-decadal to multi-centennial) variation in fire climatology (Swetnam and Brown 2010; Falk et al. 2011). Fire history and other dendroecological data also provide “historical ranges of variability” in disturbance regimes and forest structure for ecological restoration efforts intended to restore ecological processes in degraded, damaged, or mismanaged forested ecosystems (Brown et al. 2008). This is especially the case in western North America where fire suppression efforts over the past century have led to profound changes in forest and fuel structure and fire regimes in many “fire-adapted” dry conifer ecosystems (e.g., Friederici 2003).

Conclusion

Dendrochronological methods are useful for dating, reconstructing, and interpreting past fires, fire regimes, and fire effects on individuals, communities, and ecosystems. Multiple lines of evidence of fire and its effects are recorded in tree-ring series, and many of these can be dated to the exact year and even season of formation. Pyrodendroecological data are useful not only for dating of fires but, more importantly, for understanding the role of fire in ecosystem structure and function; for understanding the role of climate, human land use, and vegetation structure on variations in fire regimes; and for current and future management of ecosystems around the world.

Definition

A primary goal of the Earth sciences is to obtain as highly resolved correlations between different regions as possible. One of the most useful tools in this pursuit is the numerous fossils contained in most sedimentary units. The concept of using index fossils was initiated by the work of William Smith in the early 1800s; he used the fossil content of the units he examined as a critical component in the development of the first geologic map of the United Kingdom (Smith 1815). His observations on the distribution of fossils through time was formalized in his principle (or law) of faunal succession and served as the basis for determining the relative age of the rocks containing specific fossils. Building on Smith's concept, later workers used the temporal intervals defined by index fossils to represent range zones that form the basis of biostratigraphy, the science of correlation using fossils. Thus, index fossils form among the best components used in establishing a relative chronology and using that chronology to correlate globally.

Because all organisms evolve, this affords the opportunity to subdivide geologic time into a series of intervals characterized by individual, morphologically distinct species (the so-called morphospecies) into three intervals: an interval prior to their origination, one equivalent to their total temporal range, and another interval subsequent to their extinction. Therefore, any fossil species has the potential to be an index fossil. The best index fossils, however, tend to have the following characteristics: (1) rapid evolution so that the temporal intervals represented are short; (2) wide geographic distribution allowing correlation over a broad area; (3) virtually instantaneous range expansion following origination and simultaneous extinction decreasing the likelihood that these boundaries are time transgressive; (4) distinctive morphologic characters allowing differentiation from related taxa; (5) mineralized skeletal elements that are preserved in the fossil record; and (6) sufficient abundance affording the likelihood of finding their remains. Few taxa display all these characteristics, but that does not preclude their biostratigraphic utility.

Throughout the Phanerozoic, a broad range of different organisms has been used as index fossils. Given the criteria outlined above, the marine organisms that have proven most effective for defining short intervals are generally those that had planktic or nektic life habits. These floating/free-swimming organisms include both microinvertebrates (e.g., planktic foraminifers, radiolarians, and coccolithophores) and macroinvertebrates (e.g., ammonoids, graptolites). However, given the importance of determining the relative age of sedimentary units, representatives of

*Email: harries@usf.edu

virtually all phyla with a fossil record have been used including bivalves, brachiopods, corals, echinoids, gastropods, and trilobites (see Kauffman and Hazel (1977) for a more detailed treatment). Within the terrestrial realm, biostratigraphy has largely been based on pollen and spores as well as mammals (the so-called land mammal ages).

Quartz

Peter J. Heaney*

Department of Geosciences, Pennsylvania State University, University Park, PA, USA

On the Earth's surface, quartz (or, more properly, alpha-quartz) is by far the most common of the crystalline forms of silicon dioxide (SiO_2), constituting 12 % of the crust by volume. Among the igneous rocks, quartz is abundant within granites, granodiorites, pegmatites, and rhyolites. The weathering and erosion of these rocks tend to concentrate quartz as sedimentary particles because of its low solubility (~10 ppm) and its mechanical durability (with a Mohs hardness of 7 out of 10). As a result, quartz is the major constituent of highly mature arenitic sandstones. Quartz also can form in sedimentary environments through the chemical precipitation of dissolved silica. The dissolution of volcanic clays or of organosiliceous tests (as are found in diatoms, radiolaria, and sponges) produces a hydrous silica gel that will transform to quartz over thousands of years through diagenetic dehydration at temperatures up to 300 °C and pressures up to 2 kb. Metamorphism of siliceous sedimentary and igneous rocks will also induce quartz crystallization, and quartz is especially abundant within quartzites, schists, and gneisses. Additionally, hydrothermal alteration and fracturing of rocks may yield massive veins of quartz.

Quartz is differentiated from other silica minerals by its crystal structure and its field of thermodynamic stability. The low-temperature variety of quartz, called alpha-quartz (or low quartz), is stable when heated up to 573 °C and when stressed to pressures of 20–30 kb. When heated at atmospheric pressure above 573 °C, quartz transforms first to a structural variant called beta-quartz (or high quartz). On further heating, beta-quartz transitions to tridymite and thence to cristobalite before melting to silica liquid at 1,727 °C. When quartz at room temperature is pressurized to ~20 kb, it transforms to coesite; above 75 kb stishovite is the stable silica phase.

Euhedral crystals of quartz appear as hexagonal prisms capped at either or both ends by hexagonal pyramids, consistent with the underlying trigonal symmetry of alpha-quartz. The atomic framework of alpha-quartz consists of Si^{4+} cations that are tetrahedrally coordinated by oxygen anions (O^{2-}). Every oxygen anion is bonded to two silicon cations, so that the tetrahedral units are corner-linked to form continuous chains. In alpha-quartz, two distinct tetrahedral chains spiral about the crystallographic *c*-axis, creating ditrigonal tunnels along this direction (Fig. 1).

Although the tight crystal structure of quartz is not amenable to substitution by such radionuclides as U or Th, the past half century has seen major progress in the use of quartz for dating materials through luminescence-based approaches. Despite its apparent chemical simplicity, natural quartz crystals host a wide variety of defects, including vacant oxygen and silicon sites, as well as substitutional and interstitial cations (particularly H, Li, Al, and Fe). When quartz crystals are exposed to ionizing radiation (alpha, beta, gamma, or cosmic), these defects can serve as traps for free electrons generated by the radiation. Irradiated quartz crystals will luminesce when an external stimulation, such as from heat or light or stress, is applied, and the electrons are evicted from their traps to recombine with an appropriate defect center. In the absence of sunlight, some electron traps in quartz are thought to persist for hundreds of thousands to perhaps millions or

*Email: pjheaney@psu.edu

Fig. 1 Projection of the crystal structure of alpha-quartz along the crystallographic *c*-axis. Silicon atoms are *violet balls* and oxygen atoms are *red balls*

billions of years. The concentration of trapped electrons (and hence the intensity of the stimulated luminescence) increases with higher radiation dose until saturation is reached.

Through laboratory-based determinations of the relationship between radiation dose and light response, quartz crystals have been used to date geologic materials that were removed from sunlight and subsequently exposed to constant doses of ionizing radiation. Quartz-based luminescence has proven particularly successful in the chronometry of Quaternary sediments deposited by wind, water, and ice, but scientists have employed the technique for soils, volcanic rocks, and archaeological materials as well. Although many different luminescent stimuli have been experimentally investigated, heat and light are most commonly applied. Thermoluminescent (TL) dating involves heating quartz crystals at 5–20 °C/s and monitoring the temperature, wavelength, and intensity of the light emission. Most electron traps are emptied when quartz is heated above 500 °C, and emission events at 110 °C, 230 °C, 270 °C, 325 °C, and 375 °C are frequently observed. Scientists have attempted to relate these characteristic emissions to particular electron recombination centers. Optically stimulated luminescence (OSL) requires stimulation by light, typically using a laser emission in the blue-green portion of the electromagnetic spectrum, and the OSL emission occurs in the ultraviolet.

Recent studies have increased the sophistication of luminescence dating by combining these approaches (e.g., thermally transferred optically stimulated luminescence, or TT-OSL) and by analyses of multiple aliquots of a given sample. In addition to improving precision and accuracy, scientists hope that these approaches will extend the reach of quartz luminescence dating to a few million years.

Definition

Human evolution (molecular clocks). The timescale of human evolution and migration can be estimated from genetic data that have been sampled from living, historical, and ancient humans. This can be done using statistical methods based on the molecular clock hypothesis.

Introduction

The timescale of human evolutionary origins and migration across the globe has been a long-standing focus of scientific research. Genetic studies of the human evolutionary timescale were first performed in the 1960s, with the divergence time between humans and chimpanzees being estimated using data from the albumin protein (Sarich and Wilson 1967). The complete sequence of the human mitochondrial genome, consisting of about 16.5 thousand nucleotides, was published in 1981 (Anderson et al. 1981). Two decades later, the International Human Genome Consortium (2001) released a complete draft sequence of the much larger nuclear genome, comprising 3.2 billion nucleotides. DNA sequences of mitochondrial and nuclear genomes have now been obtained from a range of individuals throughout the world. The availability of genetic data from ancient samples has also been growing steadily (see “[Timescale of Human Evolution and Migration](#)” below).

Evolutionary timescales can be estimated from DNA sequence data using methods based on the molecular clock. The molecular clock hypothesis states that the rate of molecular evolution is constant among lineages (Zuckerkandl and Pauling 1962, 1965). If this assumption holds, then the difference between the DNA sequences of two individuals is proportional to the time since they last shared a common ancestor. If not, then there are various statistical methods that can account for rate variation among lineages and along the genome (Welch and Bromham 2005).

Until recently, genetic analyses of human prehistory were primarily based on mitochondrial DNA. The mitochondrial genome evolves rapidly and displays useful variation even over the short timescales associated with the prehistory of modern humans (Torroni et al. 2006). Substantial developments in DNA sequencing technology are enabling a growing focus on the nuclear genome, greatly increasing the data available for analysis. In addition, improving molecular techniques have made it possible to deal with contamination in ancient hominin samples. This has created opportunities to access genomic data from ancient modern humans, together with extinct species of hominins such as Neanderthals (Shapiro and Hofreiter 2010). These new sources of data have led to some significant changes to our understanding of hominin evolution. For example, DNA sequences of ancient genomes have shed light on interbreeding between Neanderthals and modern humans

*Email: simon.ho@sydney.edu.au

(Prüfer et al. 2014), our relationships with ancient hominins (Reich et al. 2010), and the timescale and patterns of human dispersals across the globe (Reich et al. 2011).

The Human Molecular Clock

For several decades, the mitochondrial genome was the dominant source of information for estimating molecular rates of evolution in humans and other hominins. In analyses of human mitochondrial genomes, a common approach is to employ an estimate of the evolutionary rate from a previous study, with a small number of “standard” rates dominating the literature (Endicott et al. 2009). Most of these rates were estimated by assuming that humans and chimpanzees diverged from each other about 6.5 million years ago, based on fossil evidence.

Pedigree studies, which involve the analysis of DNA sequences from multiple members of a family, have yielded very high estimates of mitochondrial mutation rates (Howell et al. 2003). There is a substantial discrepancy between these estimates and those based on comparisons between humans and chimpanzees. This pattern can be explained by a number of biological and statistical factors (Ho et al. 2011), including the effects of natural selection. The presence of transient deleterious mutations at the pedigree level, which are removed over time by negative selection, causes an apparent short-term elevation of evolutionary rates (Soares et al. 2009).

In analyses of mitochondrial genomes, the evolutionary rate is typically assumed to be constant among lineages. However, there is considerable evidence for rate variation among species and even among human populations (Henn et al. 2009). In addition, there are limits to the interpretation of analyses based on mitochondrial DNA, owing to the fact that it is only a single genetic marker (Balloux 2010). This is in contrast with the nuclear genome, which contains thousands of independent markers that can be used to trace evolutionary patterns and timescales.

In the post-genomic era, sequences from the nuclear genome have become readily available. This important source of data has provided a broad range of insights into human evolution. A prominent feature of genomic evolution in primates is a decline in evolutionary rates within hominoids compared with their relatives (Goodman 1985; Steiper et al. 2004). The hominoid slowdown can be partly explained by differences in generation times. In species with longer generations, the genome experiences fewer replications per unit of time. During replication, copying errors lead to mutations in the genome, and these can be inherited by descendants.

More recently, studies at the pedigree level have yielded estimates of the *de novo* mutation rate in the human nuclear genome. These have produced an unexpected result, with the *de novo* mutation rate being about half of the rate estimated using a human-chimpanzee comparison (e.g., Roach et al., 2010). A possible explanation for this pattern is that humans have longer generation times than chimpanzees, which would lead to a lower rate of evolution. This lower rate has the effect of increasing date estimates for key phases in human prehistory, such as the most recent common ancestor in Africa (Sally and Durbin 2012). The archaeological evidence for detecting population-level events in human evolution is rather scant, and it is not yet clear whether such revised dates are supported.

Timescale of Human Evolution and Migration

Estimates of the human evolutionary timescale have varied considerably, depending on the choice of genomic marker, the breadth and depth of sampling, the calibrations used for the molecular

Fig. 1 Phylogenetic tree showing the evolutionary timescale of modern humans, Neanderthal, Denisovan, and chimpanzee. *Dashed lines* indicate genetic contributions made from Neanderthals and Denisovans to populations of modern humans. Date estimates are from Prüfer et al. (2014). The tree is not drawn to scale

clock, and the method of analysis. In some cases, different date estimates support conflicting interpretations of human evolution and prehistory.

Studies of mitochondrial DNA have yielded date estimates that have been broadly consistent with the timescales inferred using archaeological and paleontological approaches. The lineage leading to modern humans diverged from Neanderthals about 400,000 years ago (Endicott et al. 2010). Living modern humans share a common mitochondrial ancestor, sometimes referred to as “mitochondrial Eve,” who lived in Africa over 100,000 years ago. Humans then migrated to Eurasia and Australasia about 50,000–60,000 years ago, reaching the Americas about 15,000 years ago.

DNA sequences from ancient specimens have had a major impact on our understanding of human prehistory. Significant advances in molecular technology have enabled entire mitochondrial and nuclear genomes to be sequenced from samples that are tens to hundreds of thousands of years old, provided that they have been preserved under certain conditions. Estimates from the nuclear genome indicate that modern humans and Neanderthals diverged more than 600,000 years ago (Fig. 1; Prüfer et al. 2014), although estimates range from 400,000 to 800,000 years. Neanderthals and another group of hominins known as Denisovans split from each other about 430,000 years ago. After this event, Neanderthals contributed genetic material to non-African modern humans, whereas significant amounts of Denisovan DNA appear only in modern humans from Oceania (Fig. 1).

Future Directions

Our understanding of the timescale of hominid and human evolution is constantly being refined. The genomic era has brought a wealth of data, offering the possibility of resolving human prehistory at an unprecedented level of detail and precision. The data being produced can yield large numbers of neutral markers for use in large-scale analyses. Additional benefits will come from further sampling of global genetic diversity, particularly in regions that are poorly represented. Genetic estimates of the human evolutionary timescale will continue to improve

with progress in identifying reliable calibrations for the human molecular clock, such as dates based on Paleolithic archaeology or biogeography. Genomic analysis of ancient human specimens represents a particularly promising area of research and has the potential to transform our understanding of the evolutionary origins of our species.

Definition

Molecular clock calibration. The temporal information used to calibrate the molecular clock and estimate the molecular substitution rate.

The Molecular Clock

Establishing an evolutionary timeline for the tree of life (TOL) is essential for understanding the history of biodiversity. The incompleteness of the rock and fossil record means this cannot be achieved using paleontological evidence alone. The molecular clock provides the only viable means of obtaining precise estimates of evolutionary time. The mutations that arise along a gene sequence represent copy errors that accumulate randomly over time. The differences observed between the genes of two living species are therefore a function of the time since they last shared a common ancestor. If the age of the last common ancestor can be determined from the fossil record for a pair of living species, the clock can be *calibrated* and the rate at which mutations have accumulated can be calculated. The molecular clock can then be used to infer the time of divergence of other species pairs. In practice, different branches of the TOL accumulate genetic changes at different rates, and precise calibrations cannot be obtained from the fossil record. Over the past 50 years, molecular clock methods have evolved to become increasingly sophisticated. Relaxed clock models can be used to accommodate rate variation, the process of molecular evolution can now be modeled more realistically, and these methods continue to be developed (Sanderson 1997, 2002; Thorne et al. 1998; Drummond et al. 2006; Rannala and Yang 2007; Drummond and Suchard 2010). There have been parallel developments in the way in which the clock is calibrated (Sanderson 1997; Thorne et al. 1998; Drummond et al. 2006; Yang and Rannala 2006; Inoue et al. 2010). Deriving paleontologically based calibrations, and quantifying the associated uncertainty, requires a careful evaluation of the way in which temporal information can be extrapolated from the fossil record (Reisz and Müller 2004; Benton and Donoghue 2007; Donoghue and Benton 2007; Parham et al. 2012).

Fig. 1 Tree illustrating the minimum and maximum divergence times among several model animal species based on fossil evidence. As an example, the divergence event between human (Actinopterygii) and zebra fish (Sarcopterygii) is highlighted. The minimum constraint (*highlighted in white*) is represented by one of the earliest known sarcopterygians, the lungfish *Diabolepis*. Minimum constraints for all divergence events are shown in **bold**; maximum dates are shown below. These examples are taken from Benton and Donoghue (2007)

Uncertainty in the Fossil Record

The fossil record is incomplete. Only a tiny fraction of all life that has ever lived has been preserved in the rock record, and some branches of the TOL are entirely absent (Raup 1972). However, the process of preservation and discovery is far from random, and the quality of the fossil record is immensely variable over geological time. There are many variables which predicate the probability that an organism will ever be preserved in the fossil record, and further obstacles that determine the probability that it will later be sampled and identified correctly by paleontologists.

Fossils are the remains of once living organisms that have been mineralized and preserved in the rock record. Different anatomical and skeletal features have variable fossilization potential, contingent on their chemical structure and the environment in which they degrade and become deposited. An organism's physiology, habitat preferences, and life history all contribute to the likelihood of preservation, and the probability of becoming fossilized can alter over time, for example, by the acquisition or loss of hard parts.

The rock record, in which the fossil record is embedded, is also spatially and temporally biased (Smith 2007), and there exists a strong, unresolved correlation between the two (Smith and McGowan 2007; Peters 2005; Benton et al. 2011). To some extent the fossil record must be subject to the artifacts of the rock record, because the appearance of an organism in the fossil record is contingent on the availability of rock units suitable for preservation and subsequent sampling (Peters and Foote 2001). Widespread heterogeneity in the deposition of sediments means the fossil record is heterogeneous both temporally and regionally. Older rocks are also more likely to have been eroded or altered by temperature and pressure. The way paleontologists sample the rock record is also influenced by the exposure and access to fossil-bearing rocks, and variable interest in different groups of fauna and formations (Dunhill 2012).

Most importantly for telling evolutionary time, the first appearance of a species in the fossil record is not coincident with the time of origin, because the probability of sampling the earliest member of a lineage is virtually zero and because it will be indistinguishable from its direct ancestor. The large number of variables that contribute to the probability that an organism will be preserved and later sampled creates huge variability in the extent of the gaps in the fossil record across the TOL. This means different fossils approximate divergence times to different degrees. Understanding the incompleteness of the fossil record forms an active and important branch of paleontology. It is important to recognize the factors that both prohibit and facilitate the process of fossilization as part of any attempt to extrapolate information from the fossil record. How we calibrate the molecular clock from such an incomplete record is not obvious.

Minimum and Maximum Constraints

The fossil record can never provide a precise time of origin for any species, but this is not equivalent to saying that the fossil record cannot provide accurate estimates. The order in which organisms first appear in the fossil record is roughly congruent with the order in which the branches of the TOL diverged genetically, meaning that the fossil record captures reality on some level (Benton et al. 2000). Using a critical approach, paleontological evidence can instead be used to constrain divergence events by providing minimum (or maximum) ages that can be incorporated into the calibration of the molecular clock (Fig. 1). First appearances provide an obvious source for defining minimum constraints, because they must postdate the time of origin of all evolutionary lineages.

An individual fossil specimen can never provide more than a minimum point of divergence, but maximum constraints are also essential for calibrating the molecular clock (Sanderson 1997; Kishino et al. 2001; Thorne and Kishino 2005; Yang and Rannala 2006). The maximum has to define the point before which evidence suggests the divergence event has not yet occurred. How far back beyond the minimum constraint is the evolutionary history of a clade likely to extend? The variable length of gaps in the fossil record makes this extremely difficult to estimate.

Maximum constraints can be established by taking into account a wider suite of paleontological evidence. One strategy is to use the fossil record of closely related evolutionary branches (phylogenetic bracketing) (Reisz and Müller 2004; Müller and Reisz 2005). The first appearance of the descendants of the proceeding divergence event may be useful for defining the maximum. This requires an assessment of the quality of the records on either side of the divergence event, because this approach relies on the assumption that there is perfect congruence between the order of branching events and the sequence in which lineages first appear in the fossil record. We know that this assumption will be violated for some species due to nonrandom preservation. An alternative, more conservative approach can be adopted to define the maximum, by tracing the record back to a time period during which conditions conducive to preservation are met, but nothing resembling the group of interest has ever been discovered, taking into account a species' ecology, biogeography, preservation potential, and sampling (Benton and Donoghue 2007; Parham et al. 2012).

Fig. 2 Definitions of crown and stem groups. The crown group (*shaded in grey*) represents all living members of a group, along with their common ancestor, and all extinct relatives in between. The stem group (*blue*) represents all the extinct members of a group that are more closely related to their crown group than to any other

The Relationship Between Fossils and Living Species

For a fossil to be useful for defining the minimum constraint of a divergence event, it must be certain that the fossil belongs to one of the descendant branches (the crown group), and not to some extinct ancestral branch that predates the point of divergence (the stem group) (Fig. 2). Understanding the evolutionary – or phylogenetic – relationships among living species is greatly facilitated by molecular sequence data; however, for organisms known only from the fossil record, relationships can only be inferred from morphological characters. This can be difficult because many extinct species are known only from very fragmentary fossil remains, or come from rocks, which have been highly eroded over time. The earliest members of a group will also be the most difficult to distinguish from the ancestral members, and in some cases the most distinguishing features of a group may be among the first to be degraded prior to fossilization (Donoghue and Purnell 2009; Sansom et al. 2010). There can also be a dramatic conflict between the relationships suggested by independent pools of phylogenetic evidence (e.g., molecular versus morphological data). If the relationship between a fossil specimen and other species (relative to the divergence event) cannot be established, that specimen cannot be used reliably to inform the minimum constraint. It is necessary to examine as much evidence as possible and use robust tree building programs to establish the relationships among fossils and living species.

Establishing the Absolute Age of a Calibration

We need to know the age of the source rock yielding the fossil specimens used to inform calibrations. It is rarely possible to derive the age directly from the specimens, so the age of the locality from where the fossil was sampled must be established. Firstly, accurate locality information must be obtained. This information varies in precision among specimens; some records will refer to a well-constrained level in a stratigraphic section, while others only indicate the relevant geological formation or group. Secondly, the age of the locality must be established. If the locality has not been directly dated (absolute dating), or the available radiometric date is not stratigraphically relevant for defining the minimum or maximum age limits, it will usually be necessary to

establish the age through stratigraphic correlation (relative dating). Once the age of the source rock is known relative to the geological timescale, the absolute age can be defined with reference to the international chronostratigraphic chart. A conservative interpretation is necessary to maintain accuracy. Minimum (or maximum) constraints should be based on the youngest (or oldest) possible interpretation of the fossil specimen. The age should correspond to the explicitly defined top (or base) of a geological time period and should include the associated radiometric dating error (Benton and Donoghue 2007; Parham et al 2012).

Tectonic Calibrations

Tectonic calibrations provide an alternative to fossil calibrations, based on the tectonic events that lead to the initial separation of two evolutionary lineages, such as the fragmentation of supercontinents, the opening of oceans, or the formation of volcanic islands. The tectonic movements that were the key to stimulating divergence among species may be manifested in the modern biogeographic ranges of the independent lineages. The use of tectonic calibrations circumvents many of the problems associated with fossil-based constraints, such as the necessity to define evolutionary relationships among extinct and living species *a priori*. But like fossil-based calibrations, the uncertainty associated with the age of tectonic events must be established, and in some cases this uncertainty can be extremely large.

Firstly, it must be established whether a given tectonic event was actually causal to the speciation event (Kodandaramaiah 2011). This requires establishing whether the modern species ranges reflect the ancestral biogeography. Tectonic events will also have variable impacts on the ecology and biogeography of different species (Goswami and Upchurch 2010). For example, an oceanic barrier might limit the dispersal of a freshwater amphibian species, but will not pose the same limitations for some bird species. The precise point at which a tectonic event becomes a complete dispersal barrier will be hard to define. Secondly, the age of the event must be established. Many tectonic events can be protracted over long episodes (e.g., tens of millions of years), and it can be difficult to pinpoint rock sources that constrain the temporal episode. The dating errors associated with the rock ages must also be considered, as above.

For groups with a very sparse fossil record, tectonic calibrations provide an excellent source, independent from the fossil record, for establishing constraints (Bromham and Penny 2003). However, fossils (perhaps of other species) will remain integral for verifying the relationship of tectonic events on modern biogeography. Tectonic calibrations should be subject to the same scrutiny with which fossil calibrations are established (Goswami and Upchurch 2010), but similarly the associated uncertainty can be quantified and modeled in molecular clock analyses.

The Development of Different Approaches to Implementing Calibrations

Traditionally calibrations were implemented as fixed points (Zuckerandl and Pauling 1962), making an assumption that there was no uncertainty associated with the calibrations and that ages obtained from the fossil record were known perfectly. However, there is often a great deal of uncertainty associated with the calibrations. Computational progress has enabled molecular clock methods to become increasingly sophisticated. Maximum likelihood approaches allowed the implementation of minimum and maximum constraints that could reflect a range of calibration ages, instead of fixed points (Sanderson 1997, 2002). There has now been a shift into the Bayesian

Fig. 3 Example calibration priors used in Bayesian molecular clock analyses. The *top panel* shows a hypothetical divergence event (*shaded in gray*) and fossil occurrences (*squares*). The oldest fossil that can be unambiguously assigned to the crown group and the minimum constraint are highlighted in *blue*. The maximum constraint is represented by the *dashed red line*. The *bottom panel* shows the prior probability functions. The y-axis represents the relative probability of divergence. In **a** and **b** the calibration prior is defined using the lognormal distribution based on the minimum constraint only (1 Ma) (**a**: $\mu = 1$; $\sigma = 0.5$; **b**: $\mu = 1.5$; $\sigma = 0.5$). **c** is an example using the skew-*t* distribution. The parameters were selected such that the 97.5 % interval matches the maximum constraint (10 Ma) ($\xi = 1$, $\omega = 2$, $\alpha = 100$, $\nu = 2.73$). **d** is an example using a uniform distribution between the minimum and maximum constraints

framework (Thorne et al. 1998; Drummond et al. 2006; Yang and Rannala 2006). The posterior probability for divergence times

$$Pr[Times | Sequence data] = Pr[Sequence data | Times] * Pr[Times] / Pr[Sequence Data]$$

combines the prior probability of divergence times ($Pr[Times]$) with the likelihood ($Pr[Sequence data | Times]$). The prior probability is used to express our prior knowledge of divergence times and contains the calibration information.

In the original Bayesian implementation, the calibrations could be implemented as minimum and maximum constraints (Thorne et al. 1998), but further development has led to increased flexibility. Each variable that describes the probability of divergence times can now be modeled independently, and all unknown parameters can be assigned an independent prior distribution

(Drummond and Rambaut 2007). The calibrations can be expressed using any of a huge variety of functions that best describe the relationship between the uncertainty inherent in the calibrations and the true divergence times (Yang and Rannala 2006; Drummond et al. 2006; Inoue et al. 2010) (Fig. 3). The uncertainty associated with all unknown parameters is considered in the estimation of evolutionary rates and times, and the output (the posterior probability) will be a distribution of values that reflects the underlying uncertainty in the estimates.

The Bayesian approach to estimating divergence times is appealing not only because it offers a great deal of flexibility, but it is also the only method that will allow the uncertainty associated with the calibrations to be reflected in the results (Thorne and Kishino 2005). Because this error can be large, this is extremely important. The way in which calibration uncertainty is represented in molecular clock analysis can have a pejorative impact on the results (Ho and Phillips 2009; Inoue et al. 2010; Clarke et al. 2011; Warnock et al. 2012). It is therefore imperative for the accurate estimation of rates and times that calibration uncertainty be accurately quantified and represented.

Characterizing the Shape of Uncertainty from the Fossil Record

Beyond establishing minimum and maximum constraints, perhaps the most challenging element of establishing molecular clock calibrations is characterizing the temporal relationship between the fossil evidence and time of origin. The function used to express the calibration prior has to reflect the probability of divergence relative to the first appearance in the fossil record. A huge variety of functions, such as the lognormal, exponential, and uniform (Fig. 3), have been integrated into Bayesian molecular clock software for this purpose. The distribution used for the calibration prior should depend on the available fossil evidence.

The minimum constraint represents the youngest possible time of divergence and can be used to define the lowest limits of the calibration prior. The peak in prior probability, representing the most likely time of divergence, occurs at some time before the first appearance in the fossil record, with a diminishing probability that divergence has occurred as you go further back in time. For an organism with a good, dense fossil record, the first appearance might provide a very good approximation of the true divergence time, so the peak in prior probability might occur close to the minimum constraint (Fig. 3a). Conversely, for a group with a very sparse record, the first appearance may provide a very poor approximation of the time of origin, and a more diffuse prior distribution might be more appropriate (Fig. 3b). In reality, it is extremely difficult to infer this relationship, and limited protocols exist for choosing the shape of the prior probability function and choosing the distribution parameters.

These parameters should not be chosen arbitrarily: a meaningful maximum constraint is also required for the estimation of the substitution rate (Sanderson 1997; Kishino et al. 2001; Thorne and Kishino 2005; Yang and Rannala 2006). A soft maximum constraint provides a useful guide for the selection of the distribution parameters, by defining the upper confidence limits of the distribution (e.g., the 95 % or 99 % limits) (Fig. 3c) (Ho and Phillips 2009; Warnock et al. 2012). However, this does not eliminate the requirement to specify the location of the peak in prior probability. In the absence of any alternative justification, a uniform distribution with an equal probability between the hard minimum and soft maximum constraints may provide the best characterization of the available evidence (Fig. 3d) (Benton and Donoghue 2007).

More comprehensive approaches are available for constructing probabilistic calibration priors based on additional phylogenetic and paleontological information. The most likely divergence time can be calculated based on the first occurrences of closely related species (Hedman 2010) or

modeled using total group fossil occurrence data (Strauss and Sadler 1989; Marshall 1997). The most complex models can incorporate estimates of speciation and extinction rates over time and nonrandom sampling of the fossil record (Foote et al. 1999; Tavaré et al. 2002; Wilkinson et al. 2010). These approaches present an excellent opportunity to integrate more paleontological evidence into the molecular estimation of divergence times, but the required comprehensive and well-curated fossil datasets are often unavailable.

Like any scientific variable based on independent sources of evidence, calibrations are dynamic values. The understanding of relationships among different branches of the TOL is continually updated, new fossil finds can update minimum or maximum constraints, and the geological timescale is perpetually refined and revised. Calibrations should be updated in light of evolving evidence.

The Inclusion of Extinct Species in the Estimation of Divergence Times

Phylogenetic tree building methods also enable the simultaneous estimation of evolutionary relationships and divergence times (Drummond et al. 2006; Ronquist et al. 2012a). However, the popular approach of incorporating calibrations in the form of prior constraints on divergence events necessitates that the relationships between the fossils and living species be known a priori. An alternative approach is to include the fossils of known age as branches in the phylogeny (Pyron 2011; Ronquist et al. 2012b). This allows the relationships of extinct and extant species, as well as the evolutionary times to be co-estimated (this is how viral trees are typically dated, using the molecular sequences of archived strains). Although molecular data can rarely be obtained from extinct or fossil specimens, morphological data can be obtained from fossils, and because living (or extant) organisms possess both sources of data, the information can be combined. The major advantage of this approach is that it eliminates the difficult quest of assigning a probability of divergence time relative to the paleontological evidence. However, this approach is accompanied by its own caveats. It requires the fossil record of the group to be relatively comprehensive, and appropriate morphological datasets are rarely available. The fragmented or eroded nature of many fossils, and the absence of any molecular data to accompany the morphological data for fossil specimens, introduces a large amount of missing data and additional uncertainty into the analysis. It also requires the assumption that a clock-like model of evolution can be applied to morphological data.

Current and Ongoing Controversies

Initially there were huge discrepancies between the evolutionary times implied by paleontological evidence and the times inferred from the molecular clock. This is partially because traditional molecular clock methods demanded the use of point (or fixed) calibrations. These were typically based on inaccurate interpretations of first appearances, and early molecular clock estimates for many groups hinted at much more ancient origins than those inferred from the fossil record alone. The timing of origin of the organisms present during and at the end of the Cambrian explosion is one notable example (which represents the first appearance of all the major animal phyla in the fossil record, around 541 Ma). Early molecular clock estimates suggested an age of more than twice that implicated by the fossil record for the origin of most animal phyla (Hedges and Kumar 2003).

The large deviations between the timescales obtained from the molecular data were initially used to denigrate the veracity of the fossil record as an accurate document of evolutionary history.

Parallel improvements in the way in which rate variation and calibration uncertainty can be modeled in molecular clock analyses have resulted in the reducing of the gap between molecular clock estimates and the fossil record. Recent estimates place the origins of the Cambrian animal fauna at 619–546 Ma (Rota-Stabelli et al. 2013). A degree of discrepancy is inevitable given the paucity of the fossil record, but the questions have now become more intellectual. How much of the fossil record can be anticipated to be missing? Could the morphology of the common ancestor of animals explain its absence from the record? A concrete collaboration between geologists and molecular biologists is essential, both for tackling these questions and for establishing a more precise timescale for the evolution of life.

In reality, we can never know the correct time of divergence relative to appearances in the fossil record, so we can never assess the accuracy of molecular clock estimates using empirical datasets. The solution is to use artificial, or simulated, datasets where the relationship between the fossil evidence and genetic divergence is known. Fossil occurrences can be simulated using a simple model of nonuniform preservation that describes the stratigraphic distribution of fossils observed in the fossil record (Holland 1995, 2000). Models of speciation, molecular sequence evolution, and fossil preservation can be combined in simulations to test different approaches to establishing calibrations and, ultimately, the performance of the molecular clock.

Summary

The incompleteness of the rock and fossil records means they cannot be used to establish a precise timeline for evolutionary history. The molecular clock provides a useful alternative, but the temporal calibrations required to estimate the substitution rate must be derived from paleontological evidence. The nonrandom nature of fossil preservation and recovery makes this extremely difficult. Although precise calibrations cannot be derived from the fossil record, they can instead be used to accurately define minimum and maximum constraints on divergence ages. The next challenge is to characterize the relationship between the constraints and divergence times. Approaches to do so have become increasingly complex and continue to progress to allow more information to be captured in the estimation of evolutionary times. Molecular estimates of times and rates will only ever be as accurate as the calibrations on which they are based, making it essential to embrace and understand the uncertainties inherent in the fossil record. Adopting a holistic approach through the integration of paleontological and biological expertise can make the molecular clock one of the most powerful tools in evolutionary biology.

Radiation and Radioactivity

Regina DeWitt*

Department of Physics, East Carolina University, Greenville, NC, USA

Definition

Radiation: The term radiation includes the whole electromagnetic spectrum as well as all atomic and subatomic particles. Ionizing radiation refers to the ability of certain types of radiation to ionize the medium they traverse. Only ionizing radiation will be considered here.

Radioactivity: The spontaneous emission of particles or electromagnetic rays from unstable atomic nuclei.

Introduction

In 1895 Wilhelm Conrad Röntgen experimented with a Crooke's tube, an evacuated glass enclosure in which current can be passed through a high vacuum from one electrode to another. He noticed that a small screen placed at some distance started fluorescing when the tube was on. Röntgen named the unknown radiation X-rays. He observed that they could penetrate paper and wood, but would be absorbed by aluminum and tin foil. Encouraged by Röntgen's observations, Henri Becquerel experimented with uranium minerals which he placed on photographic plates. He found that the plates showed signs of exposure even in the absence of light and eventually named the uranium emissions α - and β -rays. In 1897 Marie and Pierre Curie made similar observations in experiments with other elements and suggested the term "radioactivity" to describe the phenomenon. Many further discoveries have led to an increased understanding of the atomic and nuclear structure and the processes leading to the emission of ionizing radiation. Today radiation and radioactivity have found application in fields as varied as medicine, energy production, and dating.

Structure of the Nucleus

Atoms consist of a positively charged nucleus around which negative electrons revolve in stable orbits, bound by electrostatic coulomb forces due to their opposite charges. The nuclei consist of positively charged protons and electrically neutral neutrons which are collectively referred to as nucleons. The atomic number, Z , is defined as the number of protons in a nucleus. The number of neutrons is designated by the neutron number, N . The mass number, A , is the total number of nucleons in a nucleus. An arbitrary element X with atomic number Z and mass number A is denoted by ${}_Z^AX$, e.g., carbon-14 with its 6 protons and 8 neutrons is written as ${}_6^{14}\text{C}$. All nuclei of a given element have the same number of protons, but may have different numbers of neutrons. Such nuclei are referred to as isotopes (e.g., ${}_6^{12}\text{C}$, ${}_6^{13}\text{C}$, ${}_6^{14}\text{C}$).

*Email: dewitt@ecu.edu

Fig. 1 α -Decay scheme of ^{238}U to ^{234}Th . After emission of the α -particle, ^{234}Th can be left in the ground state or one of the two excited states. Decay to an excited state is followed by de-excitation and emission of γ -rays. The scheme shows possible α -energies and their emission probabilities in percent, as well as possible γ -energies (Data from Table of Nuclides, Korea Atomic Energy Research Institute)

The positive protons in the nucleus repel one another. However, the nucleus is held together as a result of the strong nuclear force. Nuclei can only exist at certain discrete energy states, similar to the energy states of the atoms themselves. The distance between these nuclear energy levels is on the order of keV or MeV while atomic levels are on the order of eV. The number of levels increases with the mass number, A . The lowest energy state is called ground level. If the nucleus is excited above this level, it can de-excite by emitting a photon and/or one or several nucleons.

The stability of a nucleus depends on its number of protons and neutrons. Nuclei of relatively small atomic numbers are most stable when the numbers of protons and neutrons are comparable. $^{12}_6\text{C}$ and $^{13}_6\text{C}$ are both stable. Heavy stable nuclei contain considerably more neutrons than protons, such as the stable bismuth isotope $^{209}_{83}\text{Bi}$, which contains 83 protons and 126 neutrons. Bismuth is the heaviest element with a stable isotope. For nuclei with $Z > 83$ the strong nuclear force can no longer compensate the repulsive forces between the protons and the nuclei disintegrate by a process of decay.

Radioactivity

Unstable nuclei emit particles until they reach a stable composition, and until stable they are “radioactive.” This process is often accompanied by a rearrangement of the nucleons within the nucleus to a lower-energy state, which leads to the emission of a high-energy photon – comparable to the emission of photons during the de-excitation of electrons. The most important decay modes are α -, β -, γ -decay, and fission.

α -decay is predominantly observed for heavier nuclei with $Z > 83$. The nucleus decays by emitting an α -particle, ^4_2He , in which process it loses two protons and two neutrons:

X is referred to as parent nuclide and Y is the daughter nuclide. For example, the parent $^{238}_{92}\text{U}$ decays to its daughter $^{234}_{90}\text{Th}$ by emitting an α -particle. The decay often leaves the daughter nuclide in one of several possible excited states, where each state is reached with different probability (see

Fig. 1). α -Particles can therefore be emitted at several discrete energies characteristic to the parent nuclide.

In **β -decay** a nucleus emits an electron or positron. β^- -decay is the conversion of a neutron to a proton, under the emission of an electron and an electron antineutrino:

It is observed for nuclides with an excess of neutrons and the process can be described by

A prominent example is the decay of radiocarbon to nitrogen: ${}_6^{14}C \rightarrow {}_7^{14}N + e^- + \bar{\nu}_e$.

β^+ -decay refers to the conversion of a proton to a neutron, under emission of a positron (i.e., the positively charged antiparticle of the electron) and an electron neutrino:

An example is the decay of ${}_{12}^{23}\text{Mg}$ to ${}_{11}^{23}\text{Na}$. Similar to α -decay, the daughter nuclide is often left in one of several possible excited states. Unlike α -particles, however, electrons and positrons do not have discrete energies. β -decay results in two particles and the energy can be divided between the particles in an infinite number of ways. Therefore β -particles are emitted with continuous energies; the spectrum is a curve with a maximum at intermediate energies and extends to an energy maximum.

α - and β -decays often leave the parent nucleus in an excited state, similar to an excited atom. The nucleus reaches a lower-energy state by rearranging the protons and neutrons and by emitting a high-energy photon, a γ -ray (compare Fig. 1). The discrete energies of these γ -rays are characteristic for the parent nuclide and are in the keV-MeV range. Neither atomic number nor mass number is changed during **γ -decay** of a nucleus.

Spontaneous **fission** is only observed for high mass numbers. In the process the nucleus splits into two smaller nuclei. Several neutrons and large amounts of energy are released during this process. For ${}^{238}\text{U}$ the probability to decay via α -decay is 10^6 times larger than the probability to undergo spontaneous fission, but this process varies among nuclides. In some nuclei such as ${}^{235}\text{U}$, fission can be induced by absorption of a slow neutron, resulting in an excited ${}^{236}\text{U}$ nucleus, which ultimately splits into two smaller nuclei.

Activity and Half-Life

Activity, A , is the rate at which unstable nuclei decay, i.e., the number of decays per second. Two units are commonly used for activity:

$$1 \text{ curie} = 1 \text{ Ci} = 3.7 \times 10^{10} \text{ decays/s}$$

which is the activity of 1 g of radium and the SI unit

Fig. 2 Thorium decay series. The nuclides, their type of decay (α or β), and their half-lives are indicated

$$1 \text{ becquerel} = 1 \text{ Bq} = 1 \text{ decay/s.}$$

The conversion factor is $1 \text{ Ci} = 3.7 \times 10^{10} \text{ Bq}$.

The number of unstable parent nuclei decreases exponentially over time. Given an initial number N_0 of parent nuclei at start time $t = 0$, the number N of nuclei remaining at time t is given by

$$N = N_0 e^{-\lambda t} \quad (6)$$

λ is referred to as the decay constant with unit s^{-1} . The larger the decay constant, the more rapidly the number of parent nuclei decreases with time. The decay constant is characteristic for each radioactive nuclide. The activity depends on the number N of nuclei and the decay constant:

$$A = \lambda N \quad (7)$$

Related to the decay constant is the half-life $t_{1/2}$ of a radioactive nucleus:

$$t_{1/2} = \frac{\ln 2}{\lambda} \quad (8)$$

The half-life is the time in which the number of parent nuclides decreases by a factor 2, i.e., from N_0 to $\frac{1}{2}N_0$ and from $\frac{1}{2}N_0$ to $\frac{1}{4}N_0$.

By determining the current number of parent and daughter nuclides in a system, it is possible to use radioactive decay in a variety of different methods to determine the age of materials. The mass m of radioactive atoms can be calculated from their activity A , their nuclide mass M , their half-life, and Avogadro's number $N_{Av} = 6.022 \times 10^{23}$:

$$m = \frac{AM}{N_{Av} \ln 2} t_{1/2} \quad (9)$$

Fig. 3 Activities $A(1)$ of nuclide 1, $A(2)$ of nuclide 2, and sum of activities when the half-life of the parent nuclide is much larger than the half-life of the daughter nuclide. Activities are normalized to the initial activity of the parent nuclide. The timescale is normalized to the half-life of the daughter nuclide. Secular radioactive equilibrium, i.e., parent and daughter have same activities, is achieved after a time equivalent to approximately eight half-lives of the daughter

Radioactive Decay Series

When a parent nucleus decays, it may decay into another radioactive nucleus. As a result, the original parent nuclide can produce a series of related nuclides which are referred to as a radioactive decay series (see “► [U-Series Dating](#)”). A famous example is the decay series of $^{238}_{92}\text{U}$ to $^{206}_{82}\text{Pb}$ (also known as the uranium-radium series). The mass number of $^{238}_{92}\text{U}$ is 238 which can be written as $4n + 2$ ($n = 59$). By variation of n all possible mass numbers in the uranium-radium series can be obtained, which is therefore often labeled $A = 4n + 2$. Other examples are $^{235}_{92}\text{U}$ to $^{207}_{82}\text{Pb}$ (uranium-actinium series, with mass numbers $A = 4n + 3$) and $^{232}_{90}\text{Th}$ to $^{208}_{82}\text{Pb}$ (mass numbers $A = 4n$).

Some nuclides can decay in two different ways, such as $^{212}_{83}\text{Bi}$ that has two daughter nuclides: $^{212}_{84}\text{Po}$ via β^- -decay and $^{208}_{81}\text{Tl}$ via α -decay. Thus within each decay series there may be multiple pathways to reach the last member of the series. Half-lives can vary considerably within one decay series. Extreme examples are $^{232}_{90}\text{Th}$ with a half-life of 1.4×10^{10} year and $^{212}_{84}\text{Po}$ with a half-life of 0.3×10^{-12} s in the same decay series. Figure 2 shows the complete thorium decay series with type of decay and half-life for each nuclide.

Radioactive Equilibria and Disequilibria

In a decay series nuclides are transformed into each other:

nuclide 1 $\rightarrow$ nuclide 2 $\rightarrow$ nuclide 3 $\rightarrow$...

Nuclide 2 (N_2) is produced through the decay of nuclide 1 (N_1), but decays simultaneously at a different rate into nuclide 3. The production rate of nuclide 2 is given by the decay rate of nuclide 1 diminished by the decay rate of nuclide 2.

Fig. 4 Activities $A(1)$ of nuclide 1, $A(2)$ of nuclide 2, and sum of activities when the half-life of the parent nuclide is five times the half-life of the daughter nuclide. Activities are normalized to the initial activity of the parent nuclide. The timescale is normalized to the half-life of the daughter nuclide. Transient radioactive equilibrium is achieved when the ratio of parent and daughter activities is constant

In a system where initially only the parent nuclide N_1 is present, daughter nuclides build up over time. Eventually an equilibrium state will be reached, where the ratio of the numbers of nuclei N_1/N_2 is constant.

$$N_2 = \frac{\lambda_1}{\lambda_2 - \lambda_1} N_1 \quad (10)$$

The time necessary to attain this radioactive equilibrium depends on the decay constants of the two nuclides. Two important cases include systems where the mother nuclide has a much longer half-life than the daughter and systems where the half-lives are comparable.

Secular radioactive equilibrium refers to cases where the half-life of the parent nuclide is much larger than that of the daughter: $t_{1/2}(1) \gg t_{1/2}(2)$. In secular radioactive equilibrium, the activities of the parent nuclide and the daughter nuclide are the same. A prominent example is the decay of ^{226}Ra (1,600 years) to ^{222}Rn (3.825 days). The gaseous radon is easily separated from its parent nuclide. Once radon is prevented from escaping, radioactive equilibrium will be established after about eight half-lives of the daughter nuclide, i.e., approximately 1 month (compare Fig. 3). In equilibrium ^{226}Ra , ^{222}Rn , and all other short-lived daughter nuclides have the same activities.

Transient radioactive equilibrium can be attained when the half-life of the parent nuclide is larger than that of the daughter, but the decay of the parent nuclide cannot be neglected: $t_{1/2}(1) > t_{1/2}(2)$. Once equilibrium is established, the activity of the daughter nuclide is larger than that of the parent nuclide (compare Fig. 4). The ratio of the activities is constant.

As the difference between the half-lives becomes smaller, the time required to reach equilibrium increases continuously. If the half-life of the parent is shorter than that of the daughter, no equilibrium can be attained.

Radioactive equilibria have several practical applications. By measuring the activity of the daughter nuclides, the activity of the parent nuclide can be determined, e.g., the amount of ^{238}U in a sample can be determined by measuring the activity of ^{234}Th . Alternatively, if activities of parent and daughter nuclides can be measured, it is possible to determine if an equilibrium state has been attained. A deviation from the equilibrium state, i.e., a disequilibrium, points toward transport of

nuclides into or out of the system. Nuclides of the decay series can be separated by natural processes if parent and daughter have different chemical behavior (e.g., uranium is soluble, thorium is particle adhesive) or if they have different probabilities of escape (the gas radon has a very high probability to escape out of a system). Recoil due to α -decay can lead to lower binding of daughters such as is the case for ^{234}U and ^{238}U .

Interaction of Radiation with Matter

Ionizing radiation can be divided into three groups – charged particles (heavy charged particles and electrons), photons, and neutrons – each of which has different mechanisms of interacting with matter.

Heavy charged particles, i.e., protons and heavier nuclei such as α -radiation, interact predominantly through coulomb forces between their positive charge and the negative charge of the electrons in the material being traversed. This leads to ionization and excitation of the target atoms. Energies required for the ionization process are on the order of several eV, i.e., the energy of visible and ultraviolet light. Radioactive decays produce radiation with energies of 0.1–10 MeV, so that α -particles produce a track with large numbers of ions and electrons. The secondary electrons released in these ionization processes are often energetic enough to cause further ionization and are often referred to as δ -radiation. Some of the charges can become trapped instead of recombining with the ions (see “► [Luminescence Dating](#)”). The ionization density of heavy charged particles is on the order of several thousand ion pairs per mm travelled. It depends on the energy lost per unit distance travelled by the ionizing particle, which is also called linear energy transfer or LET. The LET of heavy charged particles increases with distance travelled and decreases sharply after reaching a peak value, meaning α -particles interact more strongly as their velocity decreases. Due to their large mass, they are not easily deflected and their trajectory is usually a straight line with a well-defined range. A 3 MeV α -particle has a range of 1.7 cm in air and can barely penetrate a sheet of paper.

β -Radiation consists of electrons or positrons and can interact with matter in different ways including ionization and excitation of electrons in the absorbing material. Electrons can also interact with the electric field of positive nuclei under emission of bremsstrahlung. If they move through a substance with a velocity higher than the speed of light in that substance, they emit Čerenkov radiation, which is observed as deep blue light. This light is most commonly seen in open, pool-type reactors. Positrons usually annihilate with electrons in which process two gamma photons of 511 keV are emitted. Opposed to α -particles, electrons are significantly deflected by collisions with other electrons and therefore follow a zigzag path. Their range is less clearly defined. 3 MeV electrons have a range of approximately 20 m in air with an ionization density of ~ 4 ion pairs per mm and can penetrate a few millimeters of aluminum. Electrons with low energies can also experience backscattering in high-Z absorbers so that absorbers of low atomic number such as plastic or aluminum are most effective in absorbing β -radiation.

γ - and X-rays both consist of photons and have similar properties, but are distinguished by their origins: X-rays are emitted by the electron shell of atoms when electrons change from a higher- to a lower-energy orbit (characteristic X-rays) or when electrons (or other particles) are slowed down in the electric field of nuclei (bremsstrahlung). X-ray energies range from 100 eV to 100 keV. γ -Radiation is emitted during de-excitation of a nucleus, and energies range from 10 keV to 10 GeV. While particles usually lose their energy in a succession of collisions, photons mostly lose their energy in a single process. Photons interact in three different ways: In the photo effect the γ -photon

transfers its complete energy to an electron which is then emitted as a photoelectron. In the Compton effect the photon gives off only part of its energy to an electron and is then deflected into a different direction. If its energy is larger than 1.02 MeV, the photon can be transformed into an electron-positron pair (pair production). The probability for each process depends on the energy of the photon and the absorbing material. Due to the probabilistic nature of the interactions, photons have no clearly defined range. They are either removed from a beam or not. Instead of giving a range in a specific material their interaction is usually described by an absorption coefficient or their reduction in intensity: 1 MeV γ -radiation is reduced to an intensity of 1 % by 5 cm of lead or 25 cm concrete.

Neutrons are electrically neutral and interact only very weakly with electrons. They lose energy through collisions with nuclei. The neutron transfers part of its energy to the nucleus and changes its direction. This process is called scattering and leads to a slowing down of the neutrons. Scattering is most efficient in materials that contain a high amount of hydrogen, such as paraffin. Neutrons can also be absorbed by a nucleus (neutron capture). This process can lead to the formation of a stable or unstable nucleus and is used in neutron activation where radioactive nuclides are created by bombardment with neutrons (see “► [Neutron Activation Analysis](#)”). Neutrons are classified by their energy. Thermal and slow neutrons (energies >0.1 eV and 0.1–100 eV, respectively) are effectively captured by nuclei. Thermal neutron scattering is used for material characterization. Fast neutrons (0.1–10 MeV) typically lose their energy through a series of scattering events which can lead to recoil or excitation of the target nucleus. There is also a small probability for fast neutron capture. Neutrons with energies >10 MeV can cause spallation when colliding with a nucleus, in which process the target nucleus emits several nucleons with the result of leaving a lighter nucleus.

Measurement of Radiation and Radiation Dosimetry

Radiation is detected through its interaction with matter. Different methods include the ionization of gases or semiconductors and excitation of scintillators.

1. In gas-filled detectors radiation creates a trail of ion pairs. Ions and electrons are separated by applying an electric field and give rise to a current. This process is used in ionization chambers which are most effective for α - and fission fragments, proportional counters which allow quantitative measurement of α - and β -radiation, or Geiger-Muller counters for high-energy β - or X-rays (see “► [Beta Counter](#)”).
2. Scintillation detectors consist of transparent solids or liquids which emit photons when radiation is absorbed. The emitted photons are subsequently measured. Examples include NaI(Tl), CsI (Tl), and ZnS(Ag). Scintillation counters are more efficient detectors for γ -radiation than Geiger-Muller counters and are also suitable for α - and β -radiation.
3. Semiconductor detectors, such as high-purity Germanium crystals, are widely used for γ - and X-ray spectroscopy. Radiation creates charge carriers which are separated by an electric field. They are able to produce further electron hole pairs, creating an electric pulse. The pulse height is proportional to the energy of the γ -photon.

Detectors of types 2 and 3 are frequently used for spectroscopy of α - and γ -radiation to allow identification of radionuclides (see “► [Alpha Spectroscopy](#)”). Germanium detectors and NaI(Tl) scintillators are commonly used for gamma spectroscopy while alpha spectroscopy is carried out

with silicon surface barrier detectors. Due to the continuous nature of β -particles beta spectroscopy is less frequently applied. X-ray spectroscopy is carried out with Si(Li) detectors.

Other detectors such as photographic film and luminescence detectors are based on trapped electrons created by the passage of radiation. These detectors are commonly used for radiation dosimetry. Radiation dosimetry quantitatively relates radiation exposure and resulting physical, chemical, or biological changes. The primary physical quantity used is the absorbed dose. It describes the energy deposited by radiation per kg mass. Units used for dose are the SI-unit gray (Gy) and the rad:

$$1 \text{ gray} = 1\text{Gy} = 1 \text{ J/kg} = 100 \text{ rad}$$

“► [Luminescence Dating](#)” is based on measurement of absorbed dose.

Types of Nuclides

Radiation and radioactivity form the basis of many dating methods for which applications different types of nuclides and their origins have to be distinguished.

Primordial nuclides have been present from early times of the universe (see “► [Extinct Radionuclide Dating](#)”). During early stages of the universe, light elements such as H, He, Li, and Be (number of nucleons $A \leq 7$) formed in primordial nucleosynthesis. After the formation of stars, fusion processes in stellar nucleosynthesis resulted in nuclides with $A \leq 60$. Nuclides with $A > 60$ formed through neutron capture. Some of these primordial nuclides are radioactive. **Radiogenic nuclides** can be stable or radioactive and result from the decay of a parent nuclide.

The number of radioactive nuclides varies over time and their variation can be described by the laws of radioactive decay. While the concentration of the parent nuclide(s) decreases, the concentration of stable decay products increases. The decay constants are known (see “► [Radioactive Decay Constants, A Review](#)”). This forms the basis of a variety of nuclear dating methods. Suitable timescales depend on the half-lives. Examples for terrestrial parent-daughter pairs used in dating are $^{40}\text{K}/^{40}\text{Ar}$ (see “► [Ar–Ar and K–Ar Dating](#)”), $^{87}\text{Rb}/^{87}\text{Sr}$ (see “► [Rb–Sr Dating](#)”), $^{147}\text{Sm}/^{143}\text{Nd}$ (see “► [Sm–Nd Dating](#)”), $^{176}\text{Lu}/^{176}\text{Hf}$ (see “► [Lu–Hf Dating](#)”), and $^{187}\text{Re}/^{187}\text{Os}$ (see “► [Re–Os Dating](#)”).

When using these pairs it is important to take into account that daughter nuclides might already be present at $t = 0$. Usually a stable isotope of the daughter nuclide is used to calibrate initial concentrations of the decay product (see “► [Ar–Ar and K–Ar Dating](#)”).

A similar approach is used for nuclides in natural decay series. If parent and daughter nuclides show different chemical behaviors, radioactive disequilibria can be used to determine the date of separation. It is important to determine if a system is closed or open, i.e., to ensure that no losses have occurred. See for comparison “► [\$^{210}\text{Pb}\$ Dating](#),” “► [\$^{226}\text{Ra}\$ Dating, Sediment](#),” “► [U-Series Dating](#),” “► [U–Th:He Dating](#),” and “► [Uranium-Lead Dating](#).”

Nuclides in the uranium and thorium chains are also used for “► [Fission Track Dating](#)” and alpha-recoil track dating. Spontaneous or induced fission of heavy nuclei, mainly ^{238}U , can leave tracks in solids that can be made visible under a microscope by treatment with chemicals. Similarly, recoiling of atoms due to α -decay can leave a track. The track density depends on the concentration of ^{238}U and other nuclides and the time elapsed.

Another large group of nuclides that are used for dating are of cosmogenic origin (Lal 2000; Gosse and Phillips 2001; see “► [Cosmogenic Nuclide Dating](#)”). **Cosmogenic radionuclides** are continuously formed by the interaction of cosmic rays with the atmosphere and the Earth’s surface.

Cosmic radiation includes galactic cosmic rays and solar energetic particles. The galactic cosmic ray spectrum consists of approximately 85 % protons, 12 % alpha particles, 1 % heavier nuclei, and about 2 % electrons and positrons (Benton and Benton 2001). The energies range from several 10 up to 10^{12} MeV with a broad peak between 0.1 and 1 GeV. Solar energetic particles include electrons, protons, and heavier ions, and ~ 50 events can be expected in the 11-year solar cycle (for a detailed description Benton and Benton 2001).

Primary cosmic rays interact with the atmosphere and have been completely attenuated at 20 km height. They cause spallation reactions and result in secondary protons, neutrons, and muons. These secondary particles lead to further nuclear reactions in the atmosphere and can even reach the surface. In the process new nuclides are formed which can be radioactive (^3H , ^{14}C , ^{10}Be , ^{26}Al , ^{32}Si , ^{36}Cl , ^{39}Ar , ^{41}Ca , ^{81}Kr) or stable (^3He and ^{21}Ne). Prerequisite for dating based on cosmogenic nuclides is the knowledge of production rates over the time span to be dated.

Summary

The decay of primordial and radiogenic nuclides and the production of cosmogenic nuclides form the basis of various dating methods. Radioactive decay can be described by an exponential decay law. The radiation emitted in the decay process can be used to characterize the nuclides present in a system and to determine their concentrations. Radiation is detected through the interaction processes with the material it traverses.

[Martian regolith](#)

Introduction

Mars is the most Earthlike planet of the solar system and the planet most likely to have hosted life. The Martian surface exhibits abundant evidence of having undergone a complex geologic and climatic evolution. Aeolian, fluvial, periglacial, and volcanic processes appear to have remained active through to the present day, and evidence even points to active global climate change (Carr 2006). Luminescence dating has been suggested as one method to provide a chronology for Martian surface regolith, and efforts are underway to develop a robotic instrument for an in situ mission. Differences between terrestrial and Martian environments influence the dating methodology and the instrumentation required.

Mineral Composition

Unlike with terrestrial applications, an in situ luminescence dating instrument for Martian regolith samples will likely not allow chemical treatment and mineral separation. Work with polymineralic samples is a prerequisite. Data obtained by the thermal emission spectrometer distinguish two different types of regolith on Mars, namely, basaltic and andesitic, which are composed of plagioclase feldspars, pyroxenes, and hematite (Bandfield et al. 2000; Bandfield 2002). Plagioclase feldspars are found to have a calcium content of 30–70 % (Milam et al. 2004). Observations by the Spirit and Opportunity rovers further revealed a wide variety of minerals (Chevrier and Mathe 2007), some of which are believed to have formed under the influence of water. Luminescence studies used a variety of Martian simulants to approximate the type of polymineralic samples that may be found on the Martian surface, including the Martian soil simulant JSC Mars-1 (Lepper and McKeever 2000; Banerjee et al. 2002), various minerals and mineral mixtures (Kalchgruber et al. 2006; Jain et al. 2006; Blair et al. 2007; DeWitt and McKeever 2011; O'Connor et al. 2011), or basalt (Tsukamoto et al. 2011).

*Email: dewitt@ecu.edu

Measurement Procedures and Fading

In situ luminescence dating procedures for Martian regolith are limited by the polyminerallc nature of the samples and the small amounts of sample material that can be measured under the given power constraints. Kalchgruber et al. (2006) and Blair et al. (2007) found the “single-aliquot regenerative-dose” (SAR) technique suitable for polyminerallc samples. DeWitt and McKeever (2011) using mineral mixtures found that over 80 % of the blue-stimulated OSL and almost 100 % of the IR-stimulated OSL signals come from the feldspar components, so that anomalous fading is of concern. Fading can be minimized by using thermoluminescence, IR stimulation and detection in the blue wavelength range, detection of red emissions, pulsed stimulation, or IR stimulation at elevated temperatures (Jain et al. 2006; Tsukamoto and Duller 2008; Morthekai et al. 2008).

Solar Resetting

A basic premise of OSL dating is that the sediments to be dated have been exposed to sufficient amounts of light at the time of deposition to erase any previously accumulated signal. In terrestrial applications, this “zeroing” of the signal is accomplished within a few minutes of exposure to sunlight (Aitken 1998). Modeling of radiation transport in the Martian atmosphere suggested a more intense UV component at the Martian surface than is found on Earth (McKeever et al. 2006), and this may lead to different bleaching efficiencies. Carrying out experiments with a Mars solar simulator and detecting the UV luminescence, Kalchgruber et al. (2007) found efficient bleaching of the IR-stimulated signal from mineral mixtures after exposure for 1 h. When blue stimulation was used, the authors observed a non-bleachable residual signal, which was approximately 5 % of the original signal. Detschel and Lepper (2009) tested the influence of UV and a simulated Martian spectrum on the luminescence of various samples. They found that Na-feldspar (albite) tends to acquire an OSL signal with increasing UV exposure and might pose a challenge to optical dating. Ca- and K-feldspars did not acquire a significant signal under UV exposure and could be bleached when exposed to the simulated Martian spectrum. Both authors conclude that luminescence dating of Martian regolith should not be compromised by the UV-enhanced solar spectrum.

Temperature Dependence

On Earth, most minerals that are dated by OSL are found in conditions where the temperatures vary annually over a maximum range of perhaps 50 K for the entirety of their storage period. On Mars, the average ambient temperature is much lower with much larger diurnal and annual variations. Temperatures can fluctuate by 80 K within 1 day (Kieffer 1976; Hansson 1997). The global variation is reported to be from 140 to 300 K (Kieffer et al. 1992). Low-temperature OSL measurements and computer simulations indicate that known doses delivered at low temperatures can be effectively estimated if the stimulation temperature is greater than the highest temperature during irradiation (Blair et al. 2006; McKeever et al. 2010). An in situ OSL instrument must therefore provide a heating option to temperatures at least as high as 380 K.

Radiation Environment

Another challenge is the radiation environment encountered at the surface and in the regolith of Mars. Radioactive nuclides (U, Th, and K) play only a minor role in the near-surface deposits on Mars, and available data from the Mars Odyssey Gamma-Ray Spectrometer (Boynton et al. 2004; Wänke et al. 2005) will be sufficient to determine the resulting dose rate background. The primary radiation field on Mars is from galactic cosmic rays (GCR) and solar energetic particles (SEP). The GCR spectrum consists of approximately 85 % protons, 12 % alpha particles, 1 % heavier nuclei, and about 2 % electrons and positrons. The energies range from several tens up to 10^{12} MeV with a broad peak between 0.1 and 1 GeV. Solar energetic particles include electrons, protons, and heavier ions, and ~50 events can be expected in the 11-year solar cycle (for a detailed description, see, e.g., Benton and Benton 2001). This is a significant difference compared to Earth.

The efficiency of OSL signal production varies with the type of radiation. Specifically, low-energy high-Z particles have a high ionization power or large linear energy transfer (LET). Such particles are not as efficient in producing OSL signals. The high ionization density in the track of the particle as it traverses through the material leads to local saturation of the signal (Jain et al. 2006, 2007; Kalchgruber et al. 2007). The composition of the radiation and, therefore, LET change with depth due to scattering and absorption of the particles.

In terrestrial applications, ^{90}Sr beta sources are commonly used for determination of the dose response. Corrections are applied to allow for the smaller luminescence efficiency of alpha radiation compared to beta radiation. Similar corrections will be necessary when the luminescence produced by energetic particles in the cosmic radiation is compared with the calibration radiation source onboard the robotic instrument. However, cosmic ray spectra are dominated by the lower LET parts of the spectrum such that the absorbed dose is primarily (95 %) from high-energy protons and He ions. For such low-LET irradiations, the luminescence efficiency is ~1, with respect to ^{60}Co or ^{90}Sr radiation, introducing only a small error.

Dose Rate

Dose rates on the Martian surface depend upon altitude. Numbers quoted by authors vary but are of the order ~80–120 mGy/year (Saganti et al. 2004) and 43–51 mGy/year (McKeever et al. 2003; Banerjee and Dewangan 2008). The intensity and composition of the cosmic radiation field will change with increasing depth in the regolith due to absorption and scattering. At a depth of 25 g/cm², the dose rate is estimated to be 200 mGy/year, while at 700 g/cm² the dose rate is expected to be reduced to approximately 0.5 mGy/year (Pavlov et al. 2002; see also McKeever et al. 2003), which is an order of magnitude lower than the 2–12 mGy/year natural radioactivity on Earth. Various authors have carried out model calculations to determine dose rate versus depth (Dartnell et al. 2007; Mortheikai et al. 2007; Banerjee and Dewangan 2008).

Anticipated Age Limits and Uncertainties

Assuming a lower measurable dose limit of 5 Gy (Kalchgruber et al. 2007) and an average surface dose rate of 100 mGy/year (Saganti et al. 2004), the lower age limit for OSL dating can be expected to be a few decades. With an upper measurable dose limit of 1,500 Gy, the upper age limit would be only 10,000 years and, thus, considerably lower than on Earth. However, the dose rate decreases

rapidly with increasing burial depth. At 3–4 m depth and a background dose rate of 0.5 mGy/year, the upper age limit would be 3 Ma. Depending on the burial rate, the upper age limit is, therefore, expected to be in the region of several 10^5 years. Dose rate variations with depth depend on the model used but are in the range of 50 % for 2 m burial depth (McKeever et al. 2003; Morthekai et al. 2007). For an initial approximation, the age can be bracketed by calculating a minimum age based on the surface dose rate and a maximum age based on the dose rate at the depth from which the sample is recovered. An improved age value can then be determined using burial models.

Instrumentation

Robotic instrumentation for a space mission has to meet strong specifications, some of them regarding volume (max. 1,000 cm³), weight (max. 0.6 kg), power consumption (max. 10 W), and temperature range (−20 °C to 40 °C). Designs for in situ instrumentation have been suggested by Botter-Jensen et al. (2010) and DeWitt and McKeever (2011).

Both instruments use photomultipliers for detection, various light sources for stimulation, a heating element, and a miniature X-ray source for calibration of the measurements.

Summary

Luminescence dating is a suitable method to provide a chronology for Martian surface materials. The use of a robotic luminescence dating instrument for Mars requires the development of new measurement techniques in order to deal with the multiple new challenges of the Martian environment not usually found when using OSL to date terrestrial sediments. The challenges are posed, among others, by the mineral composition, the sunlight spectrum, and the radiation environment.

Luminescence, Rock Surfaces

Reza Sohbati*

Department of Geoscience, Aarhus University, Aarhus, Denmark

Center for Nuclear Technologies, Technical University of Denmark, Roskilde, Denmark

Definition

Luminescence is the light emitted following the release of stored energy (in the form of trapped charge) accumulated in crystalline materials; this energy accumulates in natural minerals such as quartz and feldspar through the absorption of ionizing radiation, either cosmic rays or resulting from the decay of naturally occurring radionuclides. This trapped charge can be released or reset by heat or light; if reset by heat, the light emitted from the mineral is called thermoluminescence (TL), and if released by photon stimulation, it is called optically stimulated luminescence (OSL). Thus, luminescence dating provides an estimate of the time elapsed since the mineral grains were last heated or exposed to daylight (Aitken 1998).

Introduction

In geology and archaeology, there are many examples of rock surfaces, rock art, and stone structures of unknown age. In archaeology, megaliths, buildings, chambered burial mounds, field walls, and cairns are very important to understanding the way in which people have used the landscape (Liritzis et al. 2013). In geology, there are examples of ice-scoured bedrock, ice-transported rocks (erratics), and cobble fans from extreme fluvial events whose ages are essential for understanding the evolution of the driving climate-related phenomena.

Luminescence dating is a well-established method of absolute chronology that has been successfully applied to a wide range of fine-grained sediments to provide depositional ages from a few years (Madsen and Murray 2009) to several tens of thousands (e.g., Murray and Olley 2002; Duller 2004) and even several hundred thousand years (e.g., Watanuki et al. 2005; Wang et al. 2006; Porat et al. 2010; Buylaert et al. 2012). The luminescence age of a sample is calculated by dividing the amount of ionizing radiation the sample absorbed during burial (measured as the equivalent dose, D_e) by the rate of energy absorption (the dose rate) from the environment. The single-aliquot regenerative dose (SAR) procedure is the standard approach to D_e determination in quartz and feldspar (Murray and Wintle 2000; Wallinga et al. 2000; Auclair et al. 2003; Buylaert et al. 2012). Dose rate calculations are dependent on the spatial distribution of energy deposition rates by the various radiations (α , β , γ). Aitken (1985) outlines an approach to such calculations near interfaces (including buried rock surfaces), although later authors suggest that the details of this approach may require modification (Yang et al. 1998).

*Email: resih@dtu.dk

Development of the Luminescence Dating of Rock Surfaces

Early attempts to date buried rock surfaces used the TL signal from calcitic rocks; this approach was based on the idea that the signal was lost as a result of exposure to daylight before burial. Liritzis (1994) proposed the use of TL to date the construction of a megalithic limestone building. Similarly, attempts were made to determine the ages of the Apollo Temple at Delphi (Liritzis et al. 1997) and of limestone pyramids in Greece (Theocaris et al. 1997). However, even after long exposures to sunlight, a significant residual TL signal remains (Liritzis and Galloway 1999); this significantly limits the youngest ages that can be determined using this method. To circumvent this problem, later studies investigated the potential of the OSL signal; it was known from the earliest days of sediment dating that this signal bleaches much more quickly and to a much lower level than TL signals (e.g., Huntley et al. 1985). First attempts were reported by Huntley and Richards (1997) in which they tried to determine the burial age of quartzite pebbles using OSL. They showed that there can be sufficient light penetration for OSL dating to be used on a surface layer. However, for most of their samples, the quartz gave so little luminescence in response to optical stimulation that their attempts to obtain reliable equivalent doses did not succeed. Trying to develop a nondestructive surface dating method, Habermann et al. (2000) built a new measurement instrument with which they measured an infrared-stimulated luminescence (IRSL) signal from the surface of a granitic rock; they related this to the dose accumulated since the last exposure to light. They also showed that almost complete bleaching to a depth of at least 2 mm can result from only a few minutes of exposure to sunlight. Morgenstein et al. (2003) used IRSL to date the fine-grained feldspar fraction scraped off the uppermost part from the bleached surface of lithic artifacts. However, the ages they obtained were not in agreement with the available age controls. They attributed this to anomalous fading (unexpected loss of signal due to quantum tunneling phenomenon in feldspars) and partial bleaching of feldspar grains. Following the idea proposed by Habermann et al. (2000), Greilich et al. (2005) used a high-spatial-resolution detection technique (HR-OSL) for OSL based on a CCD camera system to date a stone wall of the medieval castle of Lindenfels in southwestern Germany and the pre-Columbian Nasca lines (geoglyphs) around Palpa in southern Peru. Using the infrared-stimulated yellow emission from their samples, they obtained some ages in agreement with archaeological age control. However, they did not take into account anomalous fading which is known to be very common (if not universal; Huntley and Lian 2006) in the IRSL signals from feldspars. Vafiadou et al. (2007) obtained useful signals from granitic rocks using the blue stimulated ultraviolet (UV) signal originating from whole rock slices and reported complete daylight bleaching up to a depth of 5 mm after 14 days of exposure to sunlight for all of their samples. More studies on the application of TL and OSL signals to rock surfaces from archaeological sites have been carried out by Liritzis et al. (2007, 2008, 2010); however, none of these are supported by independent age control. Liritzis (2011) reviews most of these studies of luminescence rock surface dating. Simms et al. (2011) tried to reconstruct sea levels in Antarctica by measuring OSL from quartz grains obtained from the underside of cobbles within raised beaches and boulder pavements. The ages they obtained were internally consistent and agreed with radiocarbon ages. However, their quartz grains were contaminated with feldspar and they had to take into account both fading and internal dose rate (Simms et al. 2011).

In a very different approach, Polikreti et al. (2003), Polikreti (2007) suggested the possibility of using luminescence to estimate the length of time a rock surface was exposed to daylight; this would give similar information to that obtained from cosmogenic nuclide (CN) dating. While looking for a method to determine the authenticity of marble artifacts of disputed age, they investigated the bleaching of the TL signal with depth in several samples and developed a model

to describe the dependence of TL intensity on exposure time and depth; however, they were unable to estimate values for parameters in their model and so could not quantify the exposure time. Sohbaty et al. (2011) studied the depth dependence of the bleaching of the IRSL signal from granitic rocks. Using some simplifying assumptions, they presented a model of this dependence and showed it to be a good descriptor of the remaining luminescence in their naturally exposed samples. According to their model, the longer the exposure time, the further into a rock surface the luminescence is reset. However, they were unable to determine realistic estimates for some of the parameters in the model from first principles, and they did not have any sample of known exposure history with which to calibrate their model. Shortly afterward, Laskaris and Liritzis (2011) proposed a mathematical function to describe the attenuation of daylight into rock surfaces. However, their suggested approximation depends on the assumption that the residual luminescence as a function of depth into rock surfaces has a log-normal distribution, an assumption for which there does not appear to be any physical basis.

Sohbaty et al. (2012a) overcame the problem of parameter estimation by using a known-age roadcut sample for calibration. They then used the resulting parameter values to estimate the exposure times of samples of unknown age. One of their samples was a buried rock surface on which pigment from an extant rock painting was found. They were able to model the distortion in the OSL-depth resetting profile resulting from subsequent burial. This allowed them to determine a pre-burial exposure period age for their sample. This study was the first to report credible exposure ages obtained using OSL surface exposure dating. In a related study, Chapot et al. (2012) derived a burial age for the same sample by dating the outer 1-mm surface of the buried boulder. This age was supported by the OSL age of single grains of sediment buried under the boulder and by the ^{14}C age of a leaf buried between the boulder and the underlying sediment. Together, the two studies constrained the age of the Great Gallery, an archaeologically significant Barrier Canyon Style (BCS) rock art in Canyonlands National Park, Utah, USA.

As a part of an investigation into the burial age of an alluvial cobble pavement at an archaeological site in Portugal, Sohbaty et al. (2012b) further developed their model to include the environmental dose rate. The new model successfully described the variation of dose with depth and time into a quartzite cobble and allowed them to identify and quantify four events (two light exposures of different durations and two sequential burial periods) in the dose record contained within a single clast. Sohbaty et al. (2012b) showed that, for the first time, prolonged periods of exposure can leave a distinct bleaching record in the luminescence/dose profile with depth into a rock surface and, thus, that it may be possible to identify and date multiple deposition events in one sample.

In their model, Sohbaty et al. (2012b) assume that, during daylight exposure, the rate of trapped charge accumulation from natural ionizing radiation was negligible compared to the rate of detrapping due to daylight bleaching. However, they discuss that this assumption is only valid for dating those terrestrial objects which have a short exposure history and a low environmental dose rate. In considering the potential application of their technique in dating non-terrestrial surfaces, where environmental dose rates can be orders of magnitude greater than that on Earth, Sohbaty et al. (2012c) further developed the OSL surface exposure dating model by including the simultaneous effect of daylight bleaching and environmental dose rate. This now represents the most complete model of OSL resetting with depth so far presented and has the potential to date non-terrestrial geomorphological features such as fault movements, rockfalls, landslides, volcanic eruptions, and crater impacts, with an upper limit to the method between 10 and 100 ka on, for example, the Martian surface.

Discussion

Despite the recent progress with luminescence dating of rock surfaces, especially the potential application of this method in surface exposure dating, a widely applicable method has not yet been agreed upon. In sample preparation, for example, some favor working with grains extracted from rock surfaces (e.g., Simms et al. 2011; Chapot et al. 2012; Sohbati et al. 2012a), while others prefer to measure 1- to 1.5-mm-thick intact slices cut from the cores drilled into the rock surfaces (e.g., Greilich et al. 2005; Vafiadou et al. 2007; Sohbati et al. 2012b). In part, this is imposed by the nature of the samples and the fact that solid slices cannot be recovered from friable rock types (e.g., Chapot et al. 2012; Sohbati et al. 2012a). However, the significance of the issue goes beyond the physical properties of rocks and sampling methods and appears to be of dosimetric importance; Sohbati et al. (2011, 2012b) report a difference between doses measured from grains and slices recovered from the same surface for two different rock types. Unfortunately, their investigation into the source of this discrepancy did not result in a conclusive answer.

The above problem also relates to the choice of a luminescence mineral. Although quartz is often the preferred dosimeter in sediment dating, it is often not sufficiently sensitive when extracted from solid rocks (e.g., Huntley and Richards 1997; Tsukamoto et al. 2011; Sohbati et al. 2011). The intensity of signals from feldspars tends to be much less dependent on geological origin and erosion history, but the dosimetry of K-rich feldspar grains extracted from rocks is complicated because the internal dose rate is very dependent on the original feldspar grain size. The *in situ* grain size information is lost during the crushing process used to separate the grains for measurement. There have been attempts to circumvent this problem by using a nondestructive technique based on high-resolution spatially resolved luminescence detection from whole rock slices at a microscale level (e.g., Habermann et al. 2000; Greilich et al. 2002, 2005). However, dose measurement at the microscale level requires dose rate determination on the same scale for age derivation (Guérin et al. 2013); this is unlikely ever to be routine because it requires complex microdosimetry modeling in rock surfaces to include beta dose rate heterogeneity (see Nathan et al. 2003). This problem does not apply to Na-rich feldspar to the same degree because of the absence of internal radioactivity. Sohbati et al. (2013) investigated the potential application of Na-rich feldspar as a potential luminescence dosimeter for the IRSL dating of rock surfaces. The elevated-temperature IRSL signal at 290 °C that they measured after an IR bleach at 50 °C (pIRIR₂₉₀ signal) in the yellow emission seemed to be the most reliable signal for dating rock surfaces in their study; however, they speculated that higher preheat and stimulation temperatures (i.e., >320 °C and 290 °C for preheat and stimulation temperatures, respectively) may result in an even more stable yellow emission signal from Na-rich feldspar.

Conclusions

Direct luminescence dating of rock surfaces is a viable method for dating various geological and archaeological phenomena, including some that cannot be dated using sediments. Depending on the rock type and the sensitivity of quartz extracted from rock surfaces, quartz OSL and Na-rich feldspar pIRIR yellow signals can be used as reliable and dosimetrically tractable signals in the OSL and IRSL dating of rock surfaces. Unlike most sediments, rock surfaces can be exposed for prolonged periods; such long exposure periods leave a distinct bleaching record in the luminescence/dose profile with depth into a cobble. Thus, the degree of bleaching of a rock surface is

recorded within that surface, and in favorable circumstances, it is possible to identify and date multiple burial and exposure events in one sample.

The new technique of OSL surface exposure dating has considerable potential in the dating of many archaeological and geological features, such as the time of construction of megaliths, agricultural land clearance and enclosure, glacial advances and retreats, phases of erosion, and other geological processes and hazards such as mass wasting and fault scarp movement. The method is also ideally suited to the problem of *in situ* measurement of the age of young ($<10^5$ years) exposed surfaces on non-terrestrial bodies.

Sm–Nd Dating

Richard W. Carlson*

Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC, USA

Definition

Samarium–neodymium dating uses the radioactive decay of ^{147}Sm to ^{143}Nd and ^{146}Sm to ^{142}Nd to measure the age of rocks and minerals and to trace and date geochemical processes responsible for the chemical differentiation of the Earth and the terrestrial planets and planetesimals.

Introduction

Introduced to the geochemical and cosmochemical communities in the early 1970s, the Sm–Nd radioactive decay systems have grown into essential tools in geochronology and particularly for the tracing of geochemical processes. A key strength of Sm–Nd dating is that it involves two rare earth elements (REE). The behavior of the REE during geologic processes is relatively well understood because, with the exception of Eu and Ce under some conditions, they all have the same ionic charge of +3 and their ionic radius changes monotonically as a function of atomic number. As a result, their fractionation from one another during silicate rock melting and crystallization is predictable. In addition, the low solubility of REE in water leads them to be relatively immobile during rock weathering and to precipitate rapidly out of seawater once delivered to the oceans by rivers. For this reason, the Nd isotopic composition of sediments precipitated from seawater, such as manganese nodules (Piepgras et al. 1979), serves as an excellent tracer for seawater circulation (Jones et al. 2008).

Because Sm and Nd behave similarly in most geologic processes, are not strongly affected by weathering processes, and diffuse through minerals relatively slowly, the Sm–Nd dating system holds promise of being more resistant to resetting than other dating systems and thus is capable of providing accurate initial formation ages for rocks with complicated metamorphic histories. This promise, in part, has been fulfilled. Forty years of application of the Sm–Nd system, however, has provided a better appreciation that not even Sm and Nd are immune to disturbance by routine geologic processes. While this can be a problem if one is trying to obtain an accurate age for an igneous rock subjected to later metamorphism, the growth of a metamorphic mineral like garnet, one of the few minerals that strongly fractionates Sm from Nd, allows the Sm–Nd system to be an extremely useful tool for determining the time of peak metamorphism in a garnet-bearing rock (see ► [Samarium–Neodymium, Metamorphic Rocks](#)). Applications of the Sm–Nd dating system range widely and touch on many fundamental questions of solid Earth and planetary science. Examples include the following: the time of Moon formation; new estimates for the bulk composition of the Earth; the nature and age of magma ocean differentiation on Earth, Mars, and the Moon; the age of the oldest terrestrial crust; the growth rate of the continental crust; age dating of mafic/ultramafic

Fig. 1 Portion of the chart of the nuclides in the Sm–Nd mass region. Numbers along the x-and y-axes indicate the number of neutrons and protons, respectively, in each nucleus with the numbers in the boxes showing the combination of neutrons and protons that establish the mass of each nuclide. *Blue boxes* identify stable isotopes. *Green boxes* are isotopes with half-lives ranging from a few days to 10^8 years. *Brown boxes* are nuclides with half-lives ranging from minutes to days. *White boxes* are nuclides with half-lives of less than a minute. The *black arrows* show the path of s-process nucleosynthesis. The *blue arrows* show one path for r-process nucleosynthesis of Nd and the *green arrows* show one path to create ^{146}Sm via p-process nucleosynthesis

rocks; the deformation history of high-grade metamorphic belts; and the patterns of ocean circulation.

Once adequate isotope ratio precisions could be obtained to resolve the radiogenic contributions to ^{143}Nd from the decay of ^{147}Sm , the system could be applied to add a temporal component to the story of REE fractionation by geologic processes that had been developed primarily in the proceeding decade. As the precision of isotope ratio measurements improved further, the even smaller variations in ^{142}Nd due to the decay of the much less abundant, and now extinct, ^{146}Sm came into use for studies of early solar system and planetary processes.

The Nuclear Basics

The REE provide an excellent example of the odd–even effect in nuclear stability. Due to the extra nuclear stability contributed by spin pairing of nucleons, an even number of either neutrons or protons in the nucleus adds to nuclear stability, whereas an odd number of either nucleon decreases nuclear stability. All REE with an even number of protons (Z) have at least four stable or long-lived isotopes, most, including Nd (Z = 60) and Sm (Z = 62), have seven (Fig. 1). The odd-Z REE have between zero (promethium (Z = 61) that does not exist in nature for this reason) and two stable isotopes. Sm and Nd also benefit from having isotopes with 82 neutrons, one of the nuclear “magic numbers” (Mayer 1950) where there is additional stability in the nuclear shell structure model. The effect is apparent in both ^{142}Nd (Z = 60, N = 82) which is the most abundant of the stable Nd isotopes though also lightest in mass, but particularly in ^{144}Sm (Z = 62, N = 82) that is a stable isotope, whereas the next three higher mass Sm isotopes are radioactive with half-lives ranging from 340 days (^{145}Sm) to geologically useful times of 68 Ma (^{146}Sm) and 106 Ga (^{147}Sm).

Table 1 Isotopic composition of Sm and Nd

Atomic weight Nd	144.2470 g/mole						

Sm and first-row Nd data from Qin et al. (2011). These Nd data are corrected for instrumental mass fractionation to ¹⁴⁶Nd/¹⁴⁴Nd = 0.7219. The second row of Nd data is for the same material, but mass fractionation corrected to ¹⁵⁰Nd/¹⁴²Nd = 0.2096 (DePaolo and Wasserburg 1976b). Atomic masses from Emsley (1991)

The isotopic compositions of Sm and Nd are listed in Table 1. Samarium-147 constitutes just slightly less than 15 atom % of Sm and so is a relatively abundant isotope. In contrast, although ¹⁴⁶Sm was present when planet formation began in the early solar system, it no longer exists in nature because its decay half-life is only 1.5 % of the age of the Earth. Neodymium presents the complication that during the development of the Sm–Nd system, two quite different values were used for mass fractionation during analysis that results in very different measured isotopic compositions for the same Nd (Table 1). In a common technique for Nd isotopic analysis, the sample Nd is loaded onto an electrically heated filament placed in the vacuum of a mass spectrometer (see ► [Thermal Ionization Mass Spectrometer](#)). At temperatures between 1,200 °C and 1,800 °C, the Nd is both evaporated and ionized from the filament. The ionized Nd is then accelerated by an electric field into the mass spectrometer where a large magnet separates the isotopes according to their mass. During evaporation/ionization, the lighter isotopes evaporate preferentially, so the Nd entering the mass spectrometer starts out enriched in light over heavy isotopes compared to the average isotopic composition of the Nd loaded onto the filament. As the analysis proceeds, the heavier Nd isotopes become progressively more abundant. The magnitude of the mass fractionation is on the order of 0.1 % to 2 % per atomic mass unit depending on the measurement technique used. The fractionation would limit isotope ratio determinations to similar precision were it not for the ability to monitor and correct for the fractionation during measurement. The degree of fractionation is determined by comparing the measured ratio of two stable isotopes against some assumed standard value for that ratio. The measured fractionation is then applied to the other isotope ratios using some model of its mass dependency (Carlson 2013). For Nd, the two approaches used assume either ¹⁴⁶Nd/¹⁴⁴Nd = 0.7219 (O’Nions et al. 1977) or ¹⁵⁰Nd/¹⁴²Nd = 0.2096 (DePaolo and Wasserburg 1976b) to measure and correct for instrumental fractionation. While the former value produces Nd isotope ratios similar to the values obtained during the first Nd isotope measurements that used the NdO⁺ ion and assumed ¹⁴⁸NdO/¹⁴⁴NdO = 0.242436 (Lugmair et al. 1975b), the latter results in ¹⁴³Nd/¹⁴⁴Nd ratios that are lower by 0.153 % for exactly the same Nd. Care must be taken to compare only data measured using the same mass fractionation correction value or correct the data to the same mass fractionation ratio, in order to accurately compare data from these two data reduction schemes. Fortunately,

the majority of data now reported uses a single fractionation correction value, most commonly $^{146}\text{Nd}/^{144}\text{Nd} = 0.7219$. Given this issue and also to more clearly express the small variations in $^{142}\text{Nd}/^{144}\text{Nd}$ and $^{143}\text{Nd}/^{144}\text{Nd}$ ratios in nature, the isotope ratios are commonly reported as “epsilon” where

$$\epsilon^{143}\text{Nd} = \left(\left(^{143}\text{Nd}/^{144}\text{Nd} \right)_{\text{SA}} / \left(^{143}\text{Nd}/^{144}\text{Nd} \right)_{\text{Chon}} - 1 \right) \times 10^4 \quad (1)$$

and

$$\epsilon^{142}\text{Nd} = \left(\left(^{142}\text{Nd}/^{144}\text{Nd} \right)_{\text{SA}} / \left(^{142}\text{Nd}/^{144}\text{Nd} \right)_{\text{Std}} - 1 \right) \times 10^4 \quad (2)$$

where “SA” is sample, “Chon” is average chondrite (Bouvier et al. 2008), and “Std” is a terrestrial Nd isotope standard, commonly JNdi (Tanaka et al. 2000). Given the very small variations in $^{142}\text{Nd}/^{144}\text{Nd}$, $\epsilon^{142}\text{Nd}$ is sometimes replaced with $\mu^{142}\text{Nd}$, which is calculated as shown in Eq. 2 except with a multiplier of 10^6 instead of 10^4 . Given the isotopic compositions and atomic weights for Sm and Nd listed in Table 1, one can transform the Sm/Nd weight ratio (ppm/ppm) into $^{147}\text{Sm}/^{144}\text{Nd}$ atomic ratio by multiplying the weight ratio by 0.6046 when data are reported relative to $^{146}\text{Nd}/^{144}\text{Nd} = 0.7219$. The multiplier is 0.6049 when Nd data are reported relative to $^{150}\text{Nd}/^{142}\text{Nd} = 0.2096$, another indication of the need for care when comparing results reported from different laboratories that use different mass fractionation corrections for Nd.

As with all elements significantly greater in mass than iron, the REE primarily are made in stellar interiors by adding neutrons to preexisting seed nuclei (Burbidge et al. 1957). This occurs through three routes depending on the neutron density of the stellar site of nucleosynthesis (Truran and Heger 2003). In the latter stages of the life of low- to moderate-mass stars (asymptotic giant branch or AGB stars) when all the hydrogen has been consumed by nuclear fusion in the core of the star, the star contracts and the core density rises until fusion of He begins. As the He is “burned” away to make carbon and oxygen, fusion moves into less dense shells surrounding the core where mixing of material from outside the stellar interior leads to reactions such as the capture of an alpha particle (a ^4He nucleus composed of two protons and two neutrons) by ^{13}C to produce ^{16}O plus a neutron. These neutrons can then be captured by heavier nuclei, which cause them to move to the neutron-rich side of the stable mixture of neutron and protons, the so-called island of β -decay stability (Fig. 1). The more neutron-rich a nucleus becomes, the more likely it is to decay by emitting an electron (β -particle) from its nucleus to transform a neutron into a proton and thus move up in mass along the island of β -decay stability. If the neutron addition occurs more slowly than the decay, the nucleus moves in stair-step fashion up the stable portion of the nuclear chart (Fig. 1). This manner of creating heavier elements is known as slow or s-process nucleosynthesis (Gallino et al. 1997; Busso et al. 2004). For example, the sequential addition of neutrons to ^{142}Nd moves the Nd up in mass through the stable Nd isotopes to ^{146}Nd . Addition of another neutron produces ^{147}Nd , an unstable nuclei with a half-life of 11 days. If no additional neutron comes in during the stability period of ^{147}Nd , it decays to ^{147}Sm , which can capture a neutron to become ^{148}Sm , and so continues to move up mass and Z in the chart of the nuclides (Fig. 1). Because of the relatively short half-life of ^{147}Nd and particularly the 1.7-h half-life of ^{149}Nd , slow neutron addition to Nd has trouble jumping over ^{147}Nd to make stable ^{148}Nd and a particularly difficult time getting past ^{149}Nd to create stable ^{150}Nd .

This is where the second style of nucleosynthesis comes in. If the neutron density gets high enough, for example, in the interior of an exploding star called a supernova, neutron capture occurs

more rapidly than β -decay, so the seed nuclei can be driven to large neutron excesses. Eventually, the half-lives of the neutron-rich isotopes become short enough that, even at these high neutron capture rates, they decay back toward stable nuclei. This more rapid or r-process nucleosynthesis (Cowan and Sneden 2004) is the primary production mechanism for the neutron-rich isotopes of Nd and Sm. The proportion of each Nd isotope created by s-process and r-process nucleosynthetic paths thus changes with mass, with the higher mass Nd isotopes being dominated by r-process production (Arlandini et al. 1999).

The final nucleosynthetic process, the p-process, is responsible for creating the proton-rich isotopes (Meyer and Zinner 2006). In the p-process, energetic photons or neutrinos in a supernova cause the transformation of a neutron into a proton. The unstable proton-rich isotope then decays by either alpha emission or electron capture until it reaches the island of nuclear stability. Both ^{144}Sm and ^{146}Sm are made only by the p-process as neither can be made by the s-process because the s-process path takes ^{146}Nd to ^{147}Sm and both are blocked by stable isotopes of Nd from being produced by the r-process.

The elements now in our solar system consist of a mixture of the elements produced by, and blown off from, individual stars either by mass outflows from AGB stars or from the ejecta of supernova explosions. The importance of this as far as Sm–Nd dating is concerned is that ^{142}Nd cannot be produced by the r-process because β -decay of neutron-rich isotopes will stop at stable ^{142}Ce , which then blocks further decay to ^{142}Nd . If the stellar contributions to Nd in the solar nebula were not perfectly mixed when planet formation began, then variable proportions of s-process and r-process stellar ejecta would cause potentially large variations in the $^{142}\text{Nd}/^{144}\text{Nd}$ ratio in the solar system that are not due to the decay of ^{146}Sm . Nucleosynthetic heterogeneity in the solar nebula is apparent in comparisons of meteorite and terrestrial Nd data (Andreasen and Sharma 2007; Carlson et al. 2007), so this cause of isotopic variation in Nd must be taken into account particularly when applying the ^{146}Sm – ^{142}Nd dating system. The ^{147}Sm – ^{143}Nd system, however, is much less sensitive to this problem, in part because the magnitude of the ^{147}Sm decay contribution to ^{143}Nd is much larger than the ^{146}Sm contribution to ^{142}Nd . In addition, because ^{143}Nd is made by a combination of s-process and r-process nucleosynthesis, its abundance is less sensitive to imperfect mixtures of the two.

Another nuclear feature of the Sm–Nd system that must be appreciated when the Sm–Nd dating technique is applied to extraterrestrial objects is that some Nd and Sm isotopes, particularly ^{149}Sm , have large thermal neutron capture cross sections. When planetary surfaces are exposed to the high-energy particles, mostly protons, known as cosmic rays, the collision of cosmic rays with atoms in the upper meters of the planet/planetesimal can knock neutrons out of the nucleus of the impacted atom. At first, the emitted neutrons will be energetic (epithermal), but collisions with other nearby atoms slow them to thermal energies that allow them to be captured by atoms with large thermal neutron capture cross sections, such as ^{149}Sm (Lingenfelter et al. 1972). On the Moon, the $^{149}\text{Sm}/^{152}\text{Sm}$ ratio can be reduced by more than 0.4 % through neutron capture, raising the $^{150}\text{Sm}/^{152}\text{Sm}$ ratio by about 0.8 % in the process (Rankenburg et al. 2006; Boyet and Carlson 2007; Hidaka and Yoneda 2007). In fact, at least some of the techniques that allowed the development of the Sm–Nd dating system originated from efforts to measure the cosmic ray exposure history of the lunar surface using neutron capture by Sm, and particularly Gd, which has even higher thermal neutron capture cross sections (Eugster et al. 1970; Lugmair and Marti 1971).

With the exception of very minor neutron capture effects in Nd (Rankenburg et al. 2006), neutron capture would have minimal affect on Sm–Nd dating were it not for the fact that the precision needed in Sm/Nd ratio determination is such that the most commonly used technique for

Fig. 2 ^{147}Sm – ^{143}Nd and ^{146}Sm – ^{142}Nd isochrons for two eucritic meteorites illustrating the need for high-precision isotopic ratio measurements in order to obtain precise isochron slopes. The data from Notsu et al. (1973a) and Lugmair et al. (1975a) are both for the Juvinas eucrite, while the data from Boyet et al. (2010) are for the related eucrite Binda

both Sm and Nd concentration measurement is isotope dilution. In isotope dilution, a known amount of a highly purified isotope of the element is added to a known weight of sample. The degree to which the ratio of the “spike” to some stable isotope of that element in the spike plus sample mixture is changed allows the calculation of the concentration of the element in the sample. Spiking low-abundance isotopes requires less of the often very expensive spike per sample in order to make a precisely measureable shift in isotopic composition, but in the case of Sm, one also aims to avoid potential interference with Nd. For this reason, ^{149}Sm is the most commonly used spike for Sm measurement by isotope dilution. Consequently, one must know the sample’s $^{149}\text{Sm}/^{152}\text{Sm}$ ratio in order to calculate an accurate concentration via this technique. Half a percent depletion in ^{149}Sm due to neutron capture will result in a calculated Sm concentration that is 0.5 % low if the neutron-induced depletion in ^{149}Sm is not taken into account. On Earth, where the atmosphere and magnetic field shield the surface from the majority of cosmic rays, the $^{149}\text{Sm}/^{152}\text{Sm}$ ratio is constant, so neutron capture is not a significant concern for terrestrial Sm–Nd dating.

Sm–Nd Decay Systematics

Both parents ^{146}Sm and ^{147}Sm decay by emitting an alpha particle from their nucleus to end up as daughters ^{142}Nd and ^{143}Nd , respectively. The standard radioactive decay equation for ^{147}Sm – ^{143}Nd dating is

$$\left(^{143}\text{Nd}/^{144}\text{Nd} \right)_p = \left(^{143}\text{Nd}/^{144}\text{Nd} \right)_0 + \left(^{147}\text{Sm}/^{144}\text{Nd} \right)_p \times (e^{\lambda t} - 1) \quad (3)$$

where the subscript “p” refers to present day and “0” to the value at $t = 0$ where t is time. Lambda is the decay constant for ^{147}Sm . For two or more materials formed at the same time and with the same initial Nd isotopic composition, for example, different minerals rapidly crystallized from a homogeneous lava, plotting the two measureable quantities in this equation – $(^{143}\text{Nd}/^{144}\text{Nd})_p$ and $(^{147}\text{Sm}/^{144}\text{Nd})_p$ – against one another will give a line whose slope is equal to $e^{\lambda t} - 1$ and the y-

intercept is the $^{143}\text{Nd}/^{144}\text{Nd}$ at the time of formation of the minerals. The line so obtained is called an isochron (Fig. 2).

Begemann et al. (2001) summarize the measurements of the half-life of ^{147}Sm by radioactive counting. Beginning around 1960, the determinations began to cluster around a mean of 106×10^9 years, which was the value adopted in one of the early Sm–Nd dating studies (Lugmair et al. 1975b) and has been in use ever since. This translates into a decay constant of $6.54 \times 10^{-12} \text{ year}^{-1}$. The value was cross-compared with U–Pb dating of the Stillwater igneous complex by Nunes (1981) who produced a zircon U–Pb age of $2,713 \pm 3 \text{ Ma}$ in comparison with the Sm–Nd isochron age of $2,701 \pm 8 \text{ Ma}$ (DePaolo and Wasserburg 1979) that changes to $2,706 \text{ Ma}$ using the $^{146}\text{Nd}/^{144}\text{Nd} = 0.7219$ fractionation correction. The overlapping Sm–Nd and U–Pb ages indicate that the ^{147}Sm decay constant currently in use produces ages within 0.5 % of those determined using the U decay system where considerable effort has gone into determining precise decay constants (Begemann et al. 2001). With a 106 billion year (Ga) half-life, the abundance of ^{147}Sm has decreased by only 3 % over the 4.568 Ga history of the solar system.

Until recently, the half-life used for ^{146}Sm was 103 ± 5 million years (Ma) (Friedman et al. 1966), but a more recent experiment derives a significantly shorter half-life of $68 \pm 7 \text{ Ma}$ (Kinoshita et al. 2012). As either half-life is significantly shorter than the age of the Earth, ^{146}Sm no longer exists in measureable quantities in natural materials. Thus, one cannot use the standard radioactive decay equation (3) in order to calculate ages from the ^{146}Sm – ^{142}Nd system. Instead, like all dating systems based on extinct radionuclides, ages from the ^{146}Sm – ^{142}Nd system utilize equations of the form

$$\left(^{142}\text{Nd}/^{144}\text{Nd}\right)\Delta t = \left(^{142}\text{Nd}/^{144}\text{Nd}\right)_0 + ^{146}\text{Sm}/^{144}\text{Nd} \times e^{-\lambda\Delta t} \quad (4)$$

Equation 4 can be expanded as

$$\left(^{142}\text{Nd}/^{144}\text{Nd}\right)\Delta t = \left(^{142}\text{Nd}/^{144}\text{Nd}\right)_0 + \left(^{146}\text{Sm}/^{144}\text{Sm}\right) \times \left(^{144}\text{Sm}/^{144}\text{Nd}\right) \times e^{-\lambda\Delta t} \quad (5)$$

Plotting the two measureable parameters in this equation – $\left(^{142}\text{Nd}/^{144}\text{Nd}\right)\Delta t$ and $\left(^{144}\text{Sm}/^{144}\text{Nd}\right)$ – against one another for a group of minerals formed at the same time and with the same $\left(^{142}\text{Nd}/^{144}\text{Nd}\right)_0$ will give a slope equal to the $^{146}\text{Sm}/^{144}\text{Sm}$ ratio at the time the minerals formed and a y-intercept equal to $\left(^{142}\text{Nd}/^{144}\text{Nd}\right)_0$. Chronologies derived from extinct nuclides thus do not give absolute ages relative to the present day, as in ^{147}Sm – ^{143}Nd , but instead give the abundance ratio of ^{146}Sm to a stable Sm isotope, ^{144}Sm , at the time the material formed. If one rock gives a slope of 0.008 and another a slope of 0.004, then the age difference between the rocks is one half-life of ^{146}Sm , or 68 Ma.

These age differences can be transformed into absolute ages if one knows the $^{146}\text{Sm}/^{144}\text{Sm}$ in the solar system at some well-dated time. For example, if one can measure an accurate ^{147}Sm – ^{143}Nd , or more commonly U–Pb, age for a given sample, then the $^{146}\text{Sm}/^{144}\text{Sm}$ ratio determined for the same sample can serve as a time marker for the declining abundance of ^{146}Sm in the early solar system. This approach is documented in Carlson and Boyet (2009). Using this approach, Boyet et al. (2010) derive a best estimate for the initial $^{146}\text{Sm}/^{144}\text{Sm}$ in the solar system of 0.0084 ± 0.005 at 4.568 Ga. This value, however, was determined using the 103 Ma half-life of ^{146}Sm . Using instead the 68 Ma half-life, the solar system initial $^{146}\text{Sm}/^{144}\text{Sm}$ calculated from the data considered by Boyet et al. (2010) is 0.0094 (Kinoshita et al. 2012). Of concern, and a topic of continuing research, is the question of whether the $^{146}\text{Sm}/^{144}\text{Sm}$ ratio was homogeneous in the solar nebula at the beginning of

Table 2 Melt–solid partition coefficients for Sm and Nd in various minerals

Mineral/basaltic melt	D(Sm)	D(Nd)	References
Olivine	0.00055	0.00022	1
Clinopyroxene	0.462	0.277	2
Garnet	1.1	0.363	2
Garnet	0.18	0.03	3
Clinopyroxene	0.23	0.14	3
Orthopyroxene	0.0056	0.015	3
Plagioclase	0.098	0.123	4
Amphibole	0.28	0.25	5
Phlogopite	0.014	0.012	5
Apatite	12	14	6
Zircon	0.38	0.2	6

The partition coefficient, D, is defined as the ratio of the concentration of the element in the solid compared to melt. References are 1, Beattie (1994); 2, Hauri et al. (1994); 3, Green et al. (2000); 4, Bindeman and Davis (2000); 5, LaTourette et al. (1995); 6, Irving (1978)

planet formation. If ^{146}Sm and other short-lived, recently synthesized radionuclides were injected into the nebula just before the start of solar system formation, then there may not have been enough time for them to have been homogeneously mixed into the nebula prior to the start of planet(esimal) formation. If not, then different $^{146}\text{Sm}/^{144}\text{Sm}$ ratios determined for different rocks could reflect, in part, the heterogeneous distribution of ^{146}Sm in the nebula. Sorting out how much of the variability in the relative abundances of ^{142}Nd in a given rock is due to the possibly heterogeneous initial abundance of ^{146}Sm , or due to different times of rock formation, is not straightforward. The best way to answer this question is to produce a series of ^{146}Sm – ^{142}Nd “ages” for various ancient solar system materials and compare the ^{146}Sm – ^{142}Nd ages with absolute ages determined by long-lived radiometric systems such as ^{147}Sm – ^{143}Nd , U–Pb, Lu–Hf, and Rb–Sr. If the absolute ages indicate the same time span as the relative ages from ^{146}Sm – ^{142}Nd , then the argument is strong that ^{146}Sm was homogeneously distributed in the nebula at the start of planet formation.

At this point, the reader may well be asking “Why bother?” with extinct radionuclide geochronology. The answer is twofold. First, the age precision provided by isochrons is proportional, among other things, to the decay constant, so short-lived radioactive decay schemes have the potential of producing much more precise ages than can be obtained from long-lived radiometric systems. Second, because the parent nuclide becomes extinct early in Earth history, radionuclide decay schemes are less sensitive to modification of parent/daughter ratios that may occur due to metamorphic events occurring long after rock formation and thus can “see through” the later events to provide information on the time of initial rock formation (O’Neil et al. 2012).

The Geochemistry and Cosmochemistry of Sm and Nd

Sm and Nd, and all the other REE, belong to the group of elements known as “refractory lithophile” elements. The “refractory” part means that both elements have high condensation temperatures (Nd = 1,602 °C, Sm = 1,590 °C; Lodders 2003) from a gas of solar composition. As the gaseous solar nebula was cooling after the formation of the Sun, both Sm and Nd were among the first elements to condense into solid grains. Because they have similar condensation temperatures, Sm and Nd should not be dramatically fractionated from one another by condensation or evaporation

processes. The “lithophile” part means that both elements are much more soluble in silicate than in iron (siderophile) or sulfide (chalcophile) melts/solids. As a consequence, a process involving metal–silicate separation, for example, core formation, should not fractionate Sm from Nd as both will stay behind in the silicate mantle. The result of this refractory lithophile behavior of the REE is that most types of primitive meteorites, whose chemistry is controlled largely by volatility and separation of metal from silicate, show a very narrow range of REE relative abundances and a very small range (approx. $\pm 3\%$) in Sm/Nd ratios (Jacobsen and Wasserburg 1980; Boyet and Carlson 2007; Bouvier et al. 2008). For this reason, primitive meteorites often are used to model the refractory lithophile element abundances of the bulk silicate Earth, that part of Earth excluding the core (McDonough and Sun 1995; Palme and O’Neill 2003). The current best estimate for the average $^{147}\text{Sm}/^{144}\text{Nd}$ ratio of primitive meteorites, and hence the solar system, is 0.1960 ± 0.0004 with a corresponding $^{143}\text{Nd}/^{144}\text{Nd} = 0.512630 \pm 11$ (Bouvier et al. 2008).

The most effective natural processes capable of separating Sm from Nd are partial melting and fractionation crystallization. The ability of minerals to fractionate a given element is expressed by their partition coefficient, which is the ratio of the concentration of an element in a mineral compared to the concentration of the same element in a melt with which the mineral is in chemical equilibrium. Table 2 lists the partition coefficients for Sm and Nd in various minerals. Most minerals have low partition coefficients for REE, meaning that the REE tend to be “incompatible” in most silicate minerals. As a result, they selectively partition into the melt during partial melting and concentrate in the residual liquid during fractional crystallization. There are exceptions in that some minerals concentrate REE, but these minerals tend to be relatively rare trace phases, with the exception of apatite that is a common minor phase in many rock types. Apatite and plagioclase prefer Nd over Sm ($D(\text{Nd}) > D(\text{Sm})$), but they are exceptions as most minerals fractionate Sm and Nd in the opposite sense. The most extreme in this sense is garnet, where the Sm partition coefficient is at least three times higher than for Nd, but can go even higher depending on the composition of the garnet (Table 2). For most other minerals, however, the difference between Sm and Nd partition coefficients is substantially less than a factor of two. The partition coefficients listed in Table 2 provide only an estimate of the values likely to operate in igneous differentiation as partition coefficients are functions of temperature, pressure, and the composition of both the mineral and melt. A particularly thorough discussion of partition coefficients and the crystal chemical parameters that determine them is given in Wood and Blundy (2003).

The similar partition coefficients for Sm and Nd in most minerals lead to relatively small variability in Sm/Nd ratio in most natural materials. For example, given the plagioclase and pyroxene partition coefficients listed in Table 2, a rock containing only plagioclase and pyroxene with a whole rock $^{147}\text{Sm}/^{144}\text{Nd} = 0.196$ (chondritic) will have $^{147}\text{Sm}/^{144}\text{Nd}$ ratios of 0.156 and 0.322 in the plagioclase and clinopyroxene, respectively. If the rock is 4.568 Ga old and today has a whole rock $^{143}\text{Nd}/^{144}\text{Nd} = 0.51263$ (chondritic), then, using Eq. 3, the rock formed with $^{143}\text{Nd}/^{144}\text{Nd} = 0.506686$. Today, the plagioclase and pyroxene have $^{143}\text{Nd}/^{144}\text{Nd} = 0.511417$ and 0.516451, respectively, a range of just under 1 % in isotopic composition. Using Eq. 5 with a modern-day whole rock $^{142}\text{Nd}/^{144}\text{Nd} = 1.141842$, solar system initial $^{146}\text{Sm}/^{144}\text{Sm} = 0.0094$ at 4.568 Ga, and $^{144}\text{Sm}/^{147}\text{Sm} = 0.20501$, the rock modeled above formed with $^{142}\text{Nd}/^{144}\text{Nd} = 1.1414573$. Today, the plagioclase and pyroxene have $^{142}\text{Nd}/^{144}\text{Nd} = 1.1417579$ and 1.1420778, respectively, a range of 0.028 %. If the rock instead formed at 1 Ga, then the present-day $^{143}\text{Nd}/^{144}\text{Nd}$ ratios of its plagioclase and pyroxene would be 0.512368 and 0.513456, respectively, a range of 0.2 %. In a 1 Ga rock, the plagioclase, whole rock, and pyroxene would have essentially identical $^{142}\text{Nd}/^{144}\text{Nd}$ ratios because the rock formed when $^{146}\text{Sm}/^{144}\text{Sm} = 1.5 \times 10^{-18}$; hence, ^{146}Sm was, in essence, extinct at 1 Ga.

Sm and Nd also can be fractionated by partial melting. In the simple case where a source rock melts to a given degree (F) and the melt is then extracted from the remaining solid, the concentration of a trace element in the liquid (C_L) compared to its concentration in the starting solid (C_O) is given by the batch melting equation

$$C_L = C_O / (F + D - FD) \quad (6)$$
